RICHARD CLAY AND SONS, LIMITED,
LONDON AND BUNGAY

INDEX

ABBADIE (A.d'), a Straight Hand, 444
Abbé (Prof. Cleveland), Cloud Heights—Kinematic Method, 398
Abbott (Dr. S. W.), on Diphtheria, 369
Abel (Sir Frederick, F.R.S.): Inaugural Address at the Annual Spring Meeting of the Iron and Steel Institute, 42; Society of Arts Albert Medal for 1889 awarded to, 184, 301
Aberration, the Constant of, 90; Influence of, upon Observations of Solar Prominences, M. Fizeau, 530
Abney (Captain W. de W., F.R.S.): Colour Measurements and Mixture, 313; Apparatus to show Greater Sensitiveness of Eye to Different Colours, 187
Aboukir, Discovery of Three Colossal Statues at, 575
Absolute and Gravitation Systems, Frederick Slate, 445
Academy's, French, 20,000 franc Prize voted to Elisée Réclus, 161
Academy of Natural Sciences of Philadelphia, 353
Acclimatization, Dr. Robert Felkin on, 508
Acclimatization of Plants, &c., in Russia, 388
Achievements in Engineering, L. F. Vernon-Harcourt, 147
Acids, Cause of Insolubility of Pure Metals in, Dr. Weeren, 259
Acoustics: the Testing of Tuning-forks, 155; on the Intensity of Sound, and the Energy used by Organ-pipes, C. K. Wead, 310; the Production of Musical Notes from Non-musical Sands, Cecil Carus-Wilson, 322
Actinotrocha, Localities where found, 416
Adami (J. George): Laboratory Reports of the Royal College of Physicians of Edinburgh, Vol. III., 73; Immunity, Natural and Acquired, 422
Adams (Matthew A.), on Diphtheria, 369
Adams (Prof. W. G., F.R.S.), Comparison of Simultaneous Magnetic Disturbances at various Observatories, and Determination of the Value of Gaussian Coefficients for those Observatories, 237
Aden, Voracity of Rats at, Capt. R. Light, 600
Admiralty, Hydrographic Department of, 500
Advertisements for Instructors, 565
Aëronautics: New Method of determining Vertical Motion of Aëronauts, A. Duboin, 144; Experimental Researches on Mechanical Flight, Prof. S. P. Langley, 277; Maxim's New Flying Machine, 303
Aerostats, New Method of determining Vertical Motion of, A. Duboin, 144
Afghanistan, Meteorology and Climatology of Northern, W. L. Dallas, 529
Africa: Major Claude M. Macdonald on the Benué and the Kibbé, 46; Ornithology of Lake Victoria Nyanza, Emin Pasha, 87; Cetaceans in African Lakes, 124, 198; an Account of the First Ascent of Kilimanjaro, by Dr. Hans Meyer, 149; the Yoruba Country, Alvan Millson, 209; a Journey in Gazaland, Denis Doyle, 209; Theodore Bent's Investigation of Zimbabye Ruins, 451; Livingstone and the Exploration of Central, H. H. Johnston, 492; Colonel Holditch on the Application of Indian Geographical Survey Methods to, 508; Mrs. French Sheldon on East, 508; Mr. Joseph Thomson's Explorations in South, 598
Agriculture: Technical Education in, Dr. W. Fream, 137; Agricultural Education, University of Oxford and, 183; how can the Weather Service best promote, M. W. Harrington, 165; Nitrification and Agricultural Chemistry, R. Warington, 190; Mr. C. A. Barber appointed Superintendent of the Agricultural Department of the Leeward Islands, 257; Agricultural Gazette of New South Wales, 303; Proceedings of the Association of Official Agricultural Chemists, 317; Agriculture in Japan, Manuring Experiments with Paddy, Dr. O. Kellner, Y. Kozai, Y. Mori, and M. Nagaoka, 353; Dairy Work in New South Wales, 436; International Agricultural Congress, 450; Agriculture in New South Wales, 451; Agricultural Entomology, Resignation of Miss Ormerod, 451, 528; Contemplated Central Agricultural Institute in Russia, 502; Victoria, Department of Agriculture, Summary of Tasks undertaken by, D. McAlpine, 529; the Farmers and the Victoria Department of Agriculture, D. A. Crichton, 550; Projected Agricultural and Mechanical College at San Paulo, Brazil, 549
Air: New Gravimetric Method of ascertaining Composition of Atmospheric, A. Leduc, 311; the Expansion and Compressibility of Atmospheric, A. W. Witkowski, 312
Air-pressure and Temperature on Summit of Sonnblick, Studies of, Dr. J. Hann, 112
Airy (Sir G. B., F.R.S.): Completion of his Ninetieth Year, 302; his Popular Astronomy, 319
Aitken (John, F.R.S.): a Method of Counting Water Particles in Fog, 119; on the Solid and Liquid Particles in Clouds, 279
Aitken (Edith), Elementary Text-book of Botany for the Use of Schools, 467
Alaska, Prof. Russell's Excursion to, 629
Albatross: the Wandering, a Remarkable Characteristic of, Sir Walter Buller, F.R.S., 502; a New Species of, Sir Walter Buller, F.R.S., 502
Albert University, the Proposed, W. T. Thiselton Dyer, F.R.S., 196; Prof. E. Ray Lankester, F.R.S., 222; Prof. G. Carey Foster, F.R.S., 223, 257; Prof. G. Croom Robertson, 248; Rev. Dr. A. Irving, 248
Alcock (Dr. A.), the Cruise of the *Investigator*, 501, 528
Alcohol, Muscular Strength diminished by, MM. Gréhant and Quinquaud, 135
Alcohol, Physiological Effects of, Dr. Samuel Wilks, 353
Alcoholism, Prof. Harald Westergaard, 484
Alexandroff (N.), the Molecular Weights of Albumen, 358
Algebra, Solutions of the Examples in Charles Smith's Elementary, A. G. Cracknell, 444
Algebra, on the Evolution of, Prof. E. W. Hyde, 470
Algeria, the Eocene Formations of, MM. Pomel and Ficheur, 264
Alkyl Sulphides in Petroleum Oil, 89
Allen (Laurence), Defective Ventilation in American Schools, 476
Allen (W. D.), Forging Press, 579
Alloy, Brilliant Purple Gold and Aluminium, Prof. Roberts-Austen, 111
Almanac, the Nautical, 593
Alphabet of Motions, J. S. Dismorr, 225
Alpine Flora, the, T. D. A. Cockerell, 6; J. Innes Rogers, 6; J. Lovel, 83
Alpine Glaciers, the Variations of, 389
Alsace Lorraine, Meteorological Service Established in, 233
Alternate Current Motors at the Frankfort International Electrical Exhibition, 615
Alum Solution, Harry Napier Draper, 446; Ch. Ed. Guillaume, 540; Shelford Bidwell, F.R.S., 565
Amber of Cedar Lake, the so-called, B. J. Harrington, 584
Ambleside, Aurora seen at, Mr. Tuckwell, 475
America: North, Fossil Insects of, with Notes on some European Species, Samuel H. Scudder, R. Lydekker, 1; American Journal of Science, 91, 189, 310, 439, 463, 584; American Meteorological Journal, 92, 165, 309, 464, 512; the Destruction of American Fauna, 113; a Geological Excursion in America, S. F. Emmons, 182; Captain Dutton and Geology in

America, 183; American Ethnological Expedition to Labrador, 185; American National Geographic Society, 281; American Journal of Mathematics, 310; Astronomy in America, 323; Appointments to Western University of Pennsylvania and Allegheny Observatory, 323; American Association for the Advancement of Science, Washington Meeting, 469; Prof. Geo. L. Goodale on some of the Possibilities of Economic Botany, 470; Section A—Mathematics and Astronomy, Prof. E. W. Hyde on the Evolution of Algebra, 470; Section B—Physics, Prof. F. E. Nipher on the Functions and Nature of the Ether of Space, 471; Section C—Chemistry, Biological Functions of the Lecithines, by Walter Maxwell, 471; Section D—Mechanical Science and Engineering, B. E. Fermor on Government Timber Tests, 471; Section E—Geology and Geography, Prof. J. J. Stevenson on the Relations of the Chemung and Catskill on the Eastern Side of the Appalachian Basin, 471; William Hallock, a Preliminary Report of Observations at the Deep Well, Wheeling, N. Va., 472; Section F—Biology, Prof. John M. Coulter on the Future of Systematic Botany, 472; Section H—Anthropology, 473; Section I—Economic Science and Statistics, 473; Defective Ventilation in American Schools, Laurence Allen, 476; American Weather Bureau, 598; Geological Society of America, 601; the International Geological Excursion in, 629; Amerrique Indians at Nicaragua, J. Crawford, 502
Ammonium Sulphovanadate, Crystallization of, Drs. Krüss and Chnmais, 19
Amphioxus, the Later Larval Development of, Arthur Willey, 21, 202
Amsterdam, Royal Academy of Sciences, 72, 144, 288
Anæsthesia, by Subcutaneous Injection of Distilled Water, Production of Local, Dr. Sleich, 452
Anatomy of Heloderma, G. A. Boulenger, 444
Anderson (Dr.), on the Constitution of Ordnance Factories, 578
Anderson (William), proposed Fellow of the Royal Society, 15
Andes, Transandine Railway across the, 87
André (Ch.), Calorimetric Research on Sugar-derived Humic Acid, 144; Contributions to the Study of Atmospheric Electricity, 240
Andrew (James), Pugnacity of Male Ostrich in the Nesting Season, 452
Andrews (Thos., F.R.S.), the Passive State of Iron and Steel, 92
Aneroid Barometer and Leibnitz, 40
Animal Chlorophyll, Dr. Ludwig von Graff, Prof. E. Ray Lankester, F.R.S., 465
Animal Life on a Coral Reef, Dr. S. J. Hickson, 90
Animals, the Evolution of, F. Priem, R. Lydekker, 243
Annelid, the Protective Device of an, Arnold T. Watson, 507
Annuaire de l'Observatoire Municipale de Montsouris, 576
Anschutz's Photographs of Rapid Movements, 352
Antarctic Expedition, Baron Nordenskiöld's proposed, 231
Anthropology: the Diminution of the Jaw in Civilized Races, 326; Opening Address in Section H, by Prof. Max Müller, at the British Association, 428; Abnormal Development of Arms and Chests of Fakaofu Islanders, presumably caused by constant Paddling, J. J. Lister, 476; Rarity of Colour Blindness in Savage Races, Dr. L. W. Fox, 477; Prof. R. K. Douglas on the Social and Religious Ideas of the Chinese, 510; Major J. W. Powell on Indian Languages, 511; the Marquis of Bute on the Language of Teneriffe, 511; Dr. E. B. Tylor, F.R.S., on Savage Religion, 511; S. E. Peal on the *Morong* of the Natives of Asam, 511; Dr. Garson on Human Remains found in Yorkshire, 511; Miss Buckland on the "Mountain Chant," 511; Dr. S. A. K. Strahan on Instinctive Criminality, 511; E. H. Man on Nicobar Pottery, 512; the Melanesians, Studies in their Anthropology and Folk-lore, Dr. R. H. Codrington, 613; Primitive Man and Stone Hammers, J. D. McGuire, 630
Antiseptic, Microcidine, a New, Prof. Berlioz, 232
Ants, White, Jackals and Jungle Cocks, 30
Aquatic Insects, some Difficulties in the Life of, Prof. L. C. Miall, 457
Arab Domination to British Rule, South Africa from, 564
Arachnida, Propulsion of Silk by Spiders, 30
Archæan Gneiss of the North-West Highlands of Scotland, Sir Archibald Geikie, F.R.S., 480
Archæology: Rock-sculptures in Scotland, Sir Herbert Maxwell, 350; Discovery of Ancient Roman Helmet in Tiber, 476; Discovery of Three Colossal Statues at Aboukir, 575; Discovery of Anglo-Saxon Skeletons near Lewes, 575; Mr. C. L. Wacker's Archæological Researches in South-West New Mexico, 576; Album de Paléographie Copte, pour servir à l'Introduction Paléographique des Actes des Martyrs de l'Egypte, Henri Hyvernat, 609; Flinders-Petrie on Exploration in Egypt, 630
Arctic Expedition, Lieutenant Peary's projected Botanical, 231
Argyll (the Duke of, F.R.S.), the Green Sandpiper, 274
Arloing (Dr. S.), Les Virus, 27
Arloing (Prof.), Alleged Danger of Consuming Milk and Meat of Tuberculous Animals, 396
Armstrong (Prof. H. E., F.R.S.): the Function of Chlorine in Acid Chlorides, 71; Bromo-derivatives of Betanaphthol, Action of Nitric Acid on Naphthol Derivatives, Formation of Nitro-keto Compounds, New Method of preparing Nitro-derivatives, Use of Nitrogen Dioxide as a Nitrating Agent, 190; Chemical Changes occurring in Planté Cell, 237; the Formation of Salts, a Contribution to the Theory of Electrolysis, and of Nature of Chemical Change in Case of Non-electrolytes, 287
Arsenic for the Preparation of Plants, Danger of using, 232
Art, Gallery of British, at South Kensington and the Science Museum, 37, 255, 388
Art, Physical Science for Artists, Prof. J. Norman Lockyer, F.R.S., 175, 227
Art, the Existing Schools of Science and, Oliver S. Dawson, 547
Artichokes, Jerusalem, at Different Periods of Growth, Variation of Composition of, G. Lechartier, 608
Ascidians, the Classification of, Prof. W. A. Herdman, 130
Ashmolean Society, 111
Asia, Prof. Vambery on British Civilization in, 88
Asiatic Wild Sheep, Specimens of, at the British Museum, 40
Assam and Burmah, Botanical Survey in, Dr. King, 549
Assam, Mr. W. L. Sclater's projected Collecting Expedition to Upper, 598
Assmann (Dr. R.), the Aspiration Psychrometer and its Use in Balloons, 512
Asteroids, New, 164, 438, 453, 504, 530, 578, 631
Astronomy: Prof. J. Norman Lockyer, F.R.S., on Some Points in the Early History of Astronomy, 8, 57, 107, 199; Apparent Flattening of the Vault of the Heavens, Prof. Reimann, 67; Astronomical Column, 69, 89, 115, 138, 164, 209, 234, 259, 283, 305, 327, 355, 391, 438, 453, 478, 504, 530, 551, 577, 601, 631; the Photography of Faint Nebulæ, 69; Variations in Latitude, Prof. Van de Sande Bakhuyzen, 69; Re-discovery of Wolf's Comet (1884 III.), 69; Annual Report of the Paris Observatory, 70; a Comet observed from Sunrise to Noon, Captain William Ellacott, 82; Annual Visitation of the Royal Observatory, Greenwich, 87, 129; the Constant of Aberration, 90; the Meridian Photometer, 115; Report of Harvard College Observatory, 115; the Solar Parallax and its related Constants, Prof. W. Harkness, 115; Observation of Passage of Mercury across Sun's Disk, May 9, 1891, D. Eginitis, 119; Determination of Solar Constant, R. Savelief, 119; Earth Currents, the Electric Railway and the Royal Observatory, William Ellis, 127; the Spectra of Double Stars, Prof. E. C. Pickering, 138; the Perseid Radiant, 138; Newly-discovered Markings on Saturn, A. Stanley Williams, 164; Partial Solar Eclipse of June 6, 1890, M. Perrotin, 168; Brooks's Comet, 1890 II., G. Rayet and L. Picart, 168; Prof. Pritchard's Report on Oxford University Observatory, 184; Observations of Wolf's Periodic Comet, 192, 478: Death of Norman Pogson, 205; Formation in Berlin of a Union of Friends of Astronomy and Cosmical Physics, 206, 507; the Capture Theory of Comets, 209; Wolf's Periodic Comet (*b* 1891), 209; the Condition of Space, Sydney Lupton, 210; the Draper Catalogue, Prof. Edward C. Pickering, 223; the Smithsonian Astro-Physical Observatory, 254; the Stellar Cluster χ Persei, 259; Lunar Inequality of Long Period owing to Action of Venus, F. Tisserand, 263; a Cause of Lunar Libration, S. E. Peal, 283; Double-Star Observations, S. W. Burnham, 283; Observations of the Zodiacal Counter Glow, E. E. Barnard, 283; Observatory of Yale University, Dr. Elkin, 283; the Great Comet of 1882, Sereno E. Bishop, 293; the Solar Corona, Dr. J. M. Schaeberle, 300; Prof. J. Norman Lockyer, F.R.S., 300: Apparent Total Disappearance of Jupiter's Satellites, C. Flammarion, 311; Popular Astronomy, by Sir George B. Airy, F.R.S., 319; Appoint-

ments to Western University of Pennsylvania and Allegheny Observatory, 323; Prize offered by Fürstlich Jablonowsky Gesellschaft, 325; Researches on the Mean Density of the Earth, Prof. A. Cornu, 327; Parallax of P Ursæ Majoris, 327; Lessons in Astronomy, C. A. Young, 342; a Magnificent Meteor, Donald Cameron, 343; the Spectrum of β Lyræ, Prof. E. C. Pickering, 355; the Polarization Theory of the Solar Corona, Prof. Frank H. Bigelow, 355; Observations of the Motion of Sirius, Prof. Vogel, 355; Return of Encke's Comet, 355; Periodic Variations of Latitudes of Solar Prominences, A. Riccò, 360; Bright Streaks on the Moon, the Astronomer-Royal for Scotland, 360; Pogson's Observations at the Madras Observatory, 388; Prof. Lodge's Pioneers of Science, 415; the Proposed Observatory on Mont Blanc, 416; Stars having Peculiar Spectra, Prof. E. C. Pickering, 438; Photography of Solar Prominences, M. Deslandres, 438; Encke's Comet (*c* 1891), Dr. Backlund, 438; a New Asteroid, 438; Jupiter and his Markings, W. F. Denning, 439; Solar Observations, Prof. Tacchini, 453; Connection between Terrestrial Magnetism and Radiant Sunlight, Prof. Frank H. Bigelow, 453; Two New Asteroids, 453; Prof. Newton on the Action of Jupiter on Comets, 453; Solar Observations, Prof. Tacchini, 453; W. E. Wilson on the Absorption of Heat in the Solar Atmosphere, 453; Dr. Copeland on Bright Streaks in the Moon, 454; Telescopic Work for Starlight Evenings, W. F. Denning, 467; the Linear Arrangement of Stars, 478; Influence that Aberration of Light may exercise on Spectroscopic Observations of Solar Prominences, M. Fizeau, 488; Distribution of Solar Phenomena during first half of 1891, P. Tacchini, 488; Messrs. Philip and Son's New Orrery, 501; Lightning Spectra, W. E. Wood, 504; Photographic Magnitudes of Stars, Dr. Scheiner, 526; Influence of Aberration upon Observations of Solar Prominences, M. Fizeau, 530; Physical Appearance of Periodic Comets, E. E. Barnard, 551; Discovery of Tempel-Swift's Comet, 551; the Sun's Motion in Space, A. M. Clerke, 572; Measurements of Lunar Radiant Heat, 577; Two New Variable Stars, Rev. T. E. Espin, 578; a New Comet, 578; the Story of the Heavens, Sir Robert Stawell Ball, F.R.S., 589; Distribution of Lunar Heat, Frank H. Very's, 601; an Astronomer's Work in a Modern Observatory, Dr. David Gill, F.R.S., 603; Tempel-Swift's Periodic Comet, G. Bigourdan, 608; Personal Equation in Transit Observations, P. Stroovant, 608; the Zodiacal Light and Auroræ, M. A. Veeder, 631; Comet *e* 1891, 631; Double Stars, 631; Jupiter's First Satellite, 631
Athens, Earthquake at, 40
Atkins (Tommy, Sen.), $W = Mg$, 493
Atkinson (Rev. J. C.), Forty Years in a Moorland Parish, 122
Atkinson (R. W.), Meeting of the British Association at Cardiff, 204
Atlantic, Pilot Chart of North, for July, 281; for September 1891, 501
Atomic Weight Determination, Stas's Work in, 134
Attachés, Engineer, to Austrian Embassies, proposed, 575
Auerbach (Prof.), the Measurement of Hardness in Transparent Bodies, 282
Aurora seen at Ambleside, Mr. Tuckwell, 475
Aurora Borealis, a Rare Phenomenon, 494, 519, 541; W. Duppa-Crotch, 614; Prof. W. N. Hartley, F.R.S., 614
Aurora, Zodiacal Light as related to, O. T. Sherman, 310
Auroræ, the Heights of, T. W. Backhouse, 541
Auroræ, Zodiacal Light and, M. A. Veeder, 631
Ausdehnungslehre, Quaternions and the, Prof. J. Willard Gibbs, 79; Prof. P. G. Tait, 105
Australia: Australasian Association for the Advancement of Science, 40, 450, 574; Exploration of Central Australia, Alexander McPhee, 67; Meteorological Service of Australasia, 88; Nest and Eggs of the Catbird, A. J. North, 207; Luminous Insects in the Australian Bush, Henry Deane, 233; Earthquake Shocks in Italy and Australia, R. L. J. Ellery, F.R.S., 272; the Australian Marsupial Mole, *Notoryctes typhlops*, Dr. P. L. Sclater, F.R.S., 449; Extraordinary Rainfall (1890) in, Charles Todd, 501; Olive Growing in, Principal Thomson, 501
Ayrton (Prof. W. E., F.R.S.): Quadrant Electrometers, 166: Alternate Current and Potential Difference Analogies in Methods of Measuring Power, 237; Construction of Non-inductive Resistances, 261
Azoimide, New Method of Preparing, Drs. Noelting and Grandmougin, 600
Azores, Earthquake in the, 475
B.Sc. Exam., Lond. Univ. 1892, Edward J. Burrell, 565
Backhouse (T. W.), the Heights of Auroras, 541
Backlund (Dr.), Encke's Comet, *c* 1891, 438
Bacteriology: Les Virus, par Dr. S. Arloing, 27; Bacteriological and Chemical Examination of Potable Waters, A. E. S. C. Newman, 74; the British Institute of Preventive Medicine, 86; Leprosy Bacillus cultivated in Serum, by Drs. Rake and Buckmaster and Surgeon-Major Thomson, 161; Bacteria and their Products, Sims Woodhead, M.D., 246; Congress of Hygiene on Bacteriology, 419; Manuel Pratique d'Analyse Bactériologique des Eaux, Dr. Miquel, Prof. Percy F. Frankland, F.R.S., 513
Bailey (G. H.), University of London, 105
Baines (A. C.), Soaring of Birds, 520
Baker (J. G., F.R.S.): Hand-book of the Ferns of Kaffraria, T. R. Sim, 75; European Botany, Vol. I., K. Richter, 100
Bakhuyzen (Prof. Van de Sande), on Variations in Latitude, 69
Ball (Sir R. Stawell, F.R.S.): on the Cause of an Ice Age, 480; the Story of the Heavens, 589
Ball (V., F.R.S.): Cetaceans in African Lakes, 198; the Koh-i-Nur, a Reply, 592
Balloons, the Aspiration Psychrometer and its Use in Balloons, Dr. R. Assmann, 512
Baltimore Fishing School, the, 549
Bang (Dr.), Tuberculosis, 395
Bangor University College, Electricity in the Physical Department, 18
Barber (Mr. C. A), appointed Superintendent of Agricultural Department of the Leeward Islands, 257
Barclay (Dr.), Death of, 435
Barlow (Dr.), Tuberculosis in Children, 397
Barnard (E. E.): Observations of the Zodiacal Counter Glow, 283; Physical Appearance of Periodic Comets, 551
Barnes (Lieutenant H. E.), Birds Nesting in Western India, 42
Barometer, the Aneroid, and Leibnitz, 40
Barometer at Ben Nevis Observatory in Relation to Wind, Dr. Buchan, 167
Barometric Depression, Erratic Track of a, Rev. W. Clement Ley, 150
Barometric Observations, Prof. Hellmann on, 66
Barrington (Sir Vincent) and Surgeon-General Bostock, the Hospital and Ambulance Organization of the Metropolitan Asylums Board for the Removal and Isolation of Infectious Diseases, 486
Basalt, the Specific Heat of, 456
Batelli's (Signor) Experiments on Water-evaporation in Sun and in Shade, 136
Bateman (Dr.), elected Associate of Paris Academy of Medicine, 351
Bateson (W.), Supernumerary Legs and Antennæ in Beetles, 188
Beam (William) and Dr. Henry Leffmann, Examination of Water for Sanitary and Technical Purposes, 102
Beare (Prof. Thomas Hudson), Translation of Luigi Cremona's Graphical Statics, 221
Beaumont on Screw Propellers, 510
Becquerel (Edmond), Death of, 39
Becquerel (Henri) on Underground Temperatures, 632
Bees and Honey-dew, F. M. Burton, 343
Bees in New Zealand, G. M. Thomson on, 19
Bees, Remarkable Instance of Frugality in, W. H. Harris, 550
Beetle, fam. Curculionidæ, as an Example of Protective Coloration, a New South Wales, Mr. Froggatt, 576
Beetles, Supernumerary Legs and Antennæ in, W. Bateson, 188
Belgian Academy of Sciences, Subjects for Prize Competition Proposed by, 136
Bell (Alfred), Post-Tertiary Marine Deposits on South Coast of England, 191
Bell (John), a Dog Story, 521
Ben Nevis Observatory in Relation to Wind, Barometer at, Dr. Buchan, 167
Ben Nevis, the Winds of, R. T. Omond, A. Rankin, 191
Bendire (C.), on the Collection, &c., of Birds' Eggs and Nests, 502
Bengal, Earthquakes in, 185
Bennett (A. R.), on Underground Parcels Delivery, 510
Bennett (Alfred W.), Aërial Roots of the Mangrove, 370
Bent's (Theodore) Investigation of Zimbabye Ruins, 451
Benué and the Kibbé, Major Claude M. Macdonald, 46
Berg (Herr), Snow-observation in Russia, 113

Bergeron (Dr.), on Diphtheria, 369
Berget (Alphonse), Photography in Colours, Prof. R. Meldola, F.R.S., 194
Berkeley (Bishop) Memorial, the, 575
Berlin: Academy of Sciences, Recent Grants by, 136; the Imperial Physical and Technical Institution at, 154; Formation of Union of Friends of Astronomy and Cosmical Physics, 206; Berlin University, 351
Berlioz (Prof.), Microcidine, a New Antiseptic, 232
Bernardinite, is it a Mineral or a Fungus?, J. S. Brown, 310
Berne, the International Geographical Congress at, 358
Berthelot (Daniel): Calorimetric Researches on Sugar-derived Humic Acid, 144; Iron-Carbonyl and Nickel-Carbonyl, 192; the Preparation of Iron-Carbonyl and Several New Reactions of Nickel-Carbonyl, 208; Heats of Combustion and Formation of Nitrobenzenes, 360; Study of Chemical Neutralization of Acids and Bases by means of their Electric Conductivities, 360
Besant (W. H., F.R.S.), Solutions of Examples in Elementary Hydrostatics, Prof. A. G. Greenhill, F.R.S., 341
Bessemer (Sir Henry), Rolling of Steel Sheets direct from the Molten Metal, 578
Besson (A.), Phosphide of Boron, 288
Best Books, the, a Contribution to Systematic Bibliography, by William Swan Sonnenschein, 5
Bezold (Prof. W. von), on the Theory of Cyclones, 437
Bible Countries, Buried Cities and, George St. Clair, 540
Bibliography: the Best Books, a Contribution towards Systematic Bibliography, by William Swan Sonnenschein, 5; a Guide Book to Books, edited by E. B. Sargant and Bernhard Wishaw, 196; Bibliography of the Chemical Influence of Light, Dr. Alfred Tuckerman, 208; Katalog der Bibliothek der Deutschen Seewarte zu Hamburg, 318; Forthcoming Scientific Books, 462, 478
Bickerton (T. H.), Colour-blindness Generally Considered, 595
Bidgood (John), *Cordylophora lacustris*, 106
Bidwell (Shelford, F.R.S.): the Effect of an Electric Discharge upon the Condensation of Steam, 95; Effect of Heat upon Magnetic Susceptibility of Nickel, 187; Alum Solution, 565
Bigelow (Prof. Frank H.): the Polarization Theory of the Solar Corona, 355; Connection between Terrestial Magnetism and Radiant Sunlight, 453
Bigourdan (G.): Observations of Wolf's Periodic Comet, 192; Tempel-Swift's Periodic Comet, 608
Biology: Miss Marshall's Bequest to the Science and Art Department, 17; Sydney Biological Station, 39; A. R. Wallace's Natural Selection and Tropical Nature, 40; Pycnogonids or Sea Spiders, 49; Animal Life on a Coral Reef, Dr. S. J. Hickson, 90; the Classification of the Tunicata in Relation to Evolution, Prof. W. A. Herdman, 130; Anatomy and Physiology of *Protopterus annectens*, Prof. W. N. Parker, 139; Nature of Excretory Processes in Marine Polyzoa, S. F. Harmer, 143; Marine Biological Association of the United Kingdom, 205; the Evolution of Animals, F. Priem, R. Lydekker, 243; Lessons in Elementary Biology, Prof. T. Jeffery Parker, F.R.S., Prof. E. Ray Lankester, F.R.S., 290; the Anatomy of the Heloderma, Dr. R. W. Shufeldt, 294; D'Arsonval on Stimulating Muscles by Means of Light, 390; Opening Address in Section D of the British Association, by Francis Darwin, F.R.S., 407; *Cordylophora lacustris*, Henry Scherren, 445; Some Difficulties in the Life of Aquatic Insects, Prof. L. C. Miall, 457; Die Organisation der Turbellaria Acœla, Dr. Ludwig von Graff, Prof. E. Ray Lankester, F.R.S., 465; Biological Functions of the Lecithines, Walter Maxwell, 471; Biological Bearings of Fact of Stronger Absorption by Water of Long than Short Light Waves, Herr Hufner, 478; Grenfell on the Structure of Diatoms, 481; Calderwood on Sea Fisheries, 481; J. T. Cunningham on the Reproduction of the Pilchard, 481; J. T. Cunningham on the Rate and Growth of Age of Sexual Maturity in Fish, 482; Prof. Herdman and J. A. Clubb on the Innervation of the Epipodial Processes of some Nudibranchiate Mollusca, 482; Prof. W. N. Parker on Respiration in Tadpoles, 482; Prof. Howes on the Classification of Fishes by their Reproductive Organs, 483; Prof. Howes on the Gills of Fishes, 483; Dr. Arthur Robinson on the Development of the Rat and the Mouse, 483; Prof. Marcus Hartog on Protoplasmic Rejuvenescence, 483; Francis Darwin, F.R.S., on the Artificial Production of Rhythm in Plants, 484; Marine Biology, the Cruise of the *Investigator*, Dr. A. Alcock, 501, 528; a Difficulty in Weismannism, Prof. Marcus Hartog, 613; Huxley Laboratory for Biological Research, and the Marshall Scholarship, 627
Birch Oil, the Manufacture of, in Connecticut, 391
Birds, Antipathy (?) of, for Colour, 31
Birds' Eggs and Nests, the Collection, &c., of, C. Bendire, 502
Birds Nesting in Western India, Lieutenant H. E. Barnes, 42
Birds, the Soaring of, S. E. Peal, 56; A. C. Baines, 52
Birds of Victoria, the Insectivorous, C. French, 162
Birds, Wild, Protection Act, 65
Birmingham School of Medicine, Account of, 18
Bishop (Sereno E.), the Great Comet of 1882, 293
Bismuth, Thermo-electric Position of, Prof. Knott, 311
Black-Earth Steppe Region of East Russia, the Northern Limits of, Korzchinsky, 326
Blackie's Science Readers, 540
Blanchard (Emile), Proofs that Asia and America have been recently connected, 335
Blanckenhorn (Dr. Max), Geology and Physical Geography of North Syria, Prof. Edward Hull, F.R.S., 99
Blanford (Henry F., F.R.S.), M. Faye's Theory of Cyclones, 348
Blow-fly, Anatomy, Physiology, Morphology, and Development of the, B. Thompson Lowne, 123
Board of Trade Committee on Electrical Standards, the Report of the, 417
Boilers, Papers on, 20
Bologna Academy: 1000 Lire Gold Medal offered by Bologna Academy for Memoir on Best Means of Fire-Prevention, 303
Bonney (Prof. T. G., F.R.S.) and General C. A. McMahon on the Crystalline Rocks of the Lizard District, 22; the Ice Age in North America, G. F. Wright, 537
Books, the Best, a Contribution to Systematic Bibliography, by William Swan Sonnenschein, 5
Books, a Guide-book to, E. B. Sargant and Bernhard Wishaw, 196
Bornet (Dr. Edouard), Linnean Society Gold Medal awarded to, 111
Börnstein (R.), Connection between Air-pressure and Horn-angle of Moon, 281
Bort (L. Teisserenc de), the Various Kinds of Gradients, 469
Bostock (Surgeon-General) and Sir Vincent Barrington, the Hospital and Ambulance Organization of the Metropolitan Asylums Board for the Removal and Isolation of Infectious Diseases, 486
Boston (U.S.), Proposed Zoological Gardens in, 18, 529
Botany: the Alpine Flora, T. D. A. Cockerell, 6; J. Innes Rogers, 6; Nuovo Giornale Botanico Italiano, 21; Botanical Text-book, 41; the Classification of Eucalypts, 41; Death of Dr. Richard Schomburgk, 65; a Concise Manual of Botany for Students of Medicine and Science, Alex. Johnstone, 75; Hand-book of the Ferns of Kaffraria, T. R. Sim, J. G. Baker, F.R.S., 75; the Alpine Flora, J. Lovel, 83; the Kew Bulletin, 87; Drawings for the Botanical Magazine bought by the Kew Museum, 86; Expedition of D. Morris to the West Indies, 87; European Botany, Vol. I., K. Richter, J. G. Baker, F.R.S., 100; Missouri Botanical Garden, 101; William Trelease, 588; Botanical Enterprise in the West Indies, 110; Botanical Society of Edinburgh, 114; Comparison of Minute Structure of Plant Hybrids with Parent Plants, Dr. J. A. Macfarlane, 119; Botanical Appointments in United States, 135; the Relationship between Plants and Animals, Prof. Stewart, F.R.S., 136; the Flora of Diamond Island, W. Botting Helmsley, F.R.S., 138; Cotton Cultivation in Russian Turkestan, 163; Diseases of the Cocoa-Nut Leaf, M. C. Potter, 167; Botanical Wall Diagrams, S.P.C.K., 173; Kinds of Cacao in Cultivation in Ceylon, Dr. Henry Trimen, F.R.S., 185; the Species of Epilobium occurring North of Mexico, Dr. Trelease, 196; Drs. Bornmüller and Sintenis's Contemplated Expedition to Greece and Turkey in Asia, Prof. Penzig's Contemplated Expedition to Massowah and Bogos, 206; the Flowers of the Pyrenees and their Fertilization by Insects, Prof. J. Macleod, 211; Disengagement of Oxygen by Plants at Low Temperatures, H. Jumelle, 216; the Spiked Star of Bethlehem (*Ornithogalum pyrenaicum*), Dr. R. A. Prior, 215; the True Nature of Callus, Spencer Moore, 216; Lieutenant Peary's Projected Botanical Expedition Afoot to the North Pole, 231; Danger of Using Arsenic for the Preparation of Plants, 232; Influence of External Factors on the Smell of Plants, Herr Regel, 232; Botanical Gazette, 236, 335,

559; Our Country's Flowers, W. J. Gordon, 247; Obituary Notice of Cardinal Haynald, 256; Flora of Tropical Africa, 257; New Indian Labiatæ, Dr. D. Prain, 258; the Vegetation of Tibet, 260; are Seedlings of *Hemerocallis fulva* Specially Variable?, Prof. Marcus M. Hartog, 274; the Origin of the Flora of Greenland, Clement Reid, 299; Relation between Insects and Forms and Characters of Flowers, T. Meehan, 335; Pines and Firs of Japan, Dr. Maxwell T. Masters, 339; Botanical Survey of India, 347; Geo-Botanical Notes on the Flora of European Russia, D. J. Litvinoff, 359; Aërial Roots of the White Mangrove, 304; Alfred W. Bennett, 370; Acclimatization in Russia, 388; Botanical Exchange Club of the British Isles, 391; Francis Darwin, F.R.S., on Growth-Curvatures in Plants, 407; Embryology of Flowering Plants, Mdlle. C. Sokolowa, 437; Botany of the Chinese Classics, 438; Abbildungen zur Deutschen Flora, H. Karsten's, 467; Elementary Text-book of Botany for the Use of Schools, Edith Aitken, 467; Some of the Possibilities of Economic Botany, Prof. Geo. L. Goodale, 469; on the Future of Systematic Botany Prof. John M. Coulter, 472; Proposed Conference on Conifers, 475; Californian Trees and Flowers, 477; Francis Darwin, F.R.S., on the Artificial Production of Rhythm in Plants, 484; Flowers and Insects, G. F. Scott-Elliott, 488; Sleep Movements in Plants, A. G. Tansley, 493; Acclimatization of the Lacquer-Tree at Frankfort, Prof. Rein, 500; American Expeditions to Investigate Flora of Mexico, 501; Olive-growing in Australia, Principal Thomson, 501; Cultivation of Tobacco in German New Guinea, 502; "Kammé," a New Species of Truffle, A. Chatin, 512; Bush Friends in Tasmania, Mrs. L. A. Meredith, 517; the Fertilization of South African and Madagascar Flowering Plants, C. F. S. Elliott, 528; the Distribution of Marine Algæ, G. Murray, 528; Oesterreichische Botanische Zeitung, 528; Dr. Palmer's Collections in Western Mexico and Arizona, 528; Some of the Possibilities of Economic Botany, Prof. George Lincoln Goodale on, 530; the Cereals, 531; Vegetables, 532; Fruits, 532; Timbers and Cabinet Woods, 534; Vegetable Fibres, 534; Tanning Materials, 534; Resins, &c., 534; Fragrant Plants, 535; Exhibition of Cone-bearing Trees, Royal Horticultural Society, 548; Dr. Prain and the *Investigator* Cruise, 549; Botanical Survey in Assam and Burmah, Dr. King, 549; Wattles and Wattle-barks, J. H. Maiden, 579; Projected International Botanical Congress at Genoa, 598; M. Paul Maury's Expedition to Mexico, 598; Variation of Composition of Jerusalem Artichokes at Different Periods of Growth, G. Lechartier, 608

Boulenger (G. A.), Anatomy of Heloderma, 444

Bournemouth, Meeting of the British Medical Association at, 161; Earthquake at, Henry Cecil, 614

Boutroux (Léon), the Fermentation of Bread, 336

Bouty (E.), Dielectric Properties of Mica at High Temperatures, 168

Bower (Frederick Orpen), Proposed Fellow of the Royal Society, 15

Boys (C. V.), Pocket Electrometers, 262

Brackett (R. N.), Newtonite and Rectorite, New Minerals of the Kaolinite Group, 310

Brandis (Sir D., F.R.S.), a Manual of Forestry, William Schlich, 265

Brass Sheets, T. Turner on Red Blotches in, 455

Brauner (Dr.), on Lanthanum, 68

Brazil, H. Morize on the Climatology of, 437

Brazil, Projected Agricultural Mechanical College at San Paulo, 549

Bread, the Fermentation of, Léon Boutroux, 336

Brezina (Dr. A.), Capture of a Supposed Gem Thief at Vienna, 598

Breweries: Proposed Utilization of Carbonic Acid produced in Fermentation of Sugar, 303

Brighton Aquarium, Birth of Sea Lion at, 185

Brinton (Dr. Daniel G.): Races and Peoples, 124; Vocabularies from the Musquito Coast, 600

Bristol University College Calendar, 438

British Art, Gallery of, at South Kensington and the Science Museum, 37, 255

BRITISH ASSOCIATION: Meeting at Cardiff, General Programme, 65, 371; Preliminary Arrangements, 204, 280; Grants of the, 423; Arrangements for the Meeting at Edinburgh in 1892, 161, 398; Inaugural Address at Cardiff by William Huggins, LL.D., F.R.S., 372

Section A (*Mathematics and Physics*)—Opening Address by Prof. Oliver J. Lodge, LL.D., F.R.S., President of the Section, 382; Prof. Newton on the Action of Jupiter on Comets, 453; W. E. Wilson on the Absorption of Heat in the Solar Atmosphere, 453; Prof. Oliver J. Lodge, F.R.S., on whether the Ether behaves as a Viscous Fluid, 454; Prof. D. E. Jones on Electric Waves in Wires, 454; Papers on Electrolysis, 454; Dr. Johnstone Stoney, F.R.S., on Double Lines in the Spectra of Gases, 454; Dr. Copeland on Bright Streaks on the Moon, 454; Prof. Oliver J. Lodge, F.R.S., on Light in Modifying the Effect of the Gravitational Attraction of the Sun, 454; Units and their Nomenclature, 454; Prof. S. P. Thompson, F.R.S., on the Measurement of Lenses, and on a New Polarizer, 455; F. T. Trouton on the Propagation of Magnetization in Iron, 455

Section B (*Chemistry*)—Opening Address by Prof. W. C. Roberts-Austen, C.B., F.R.S., President of the Section, 399; Report of the Committee on the Formation of Haloid Salts, 455; Prof. Vivian B. Lewes on the Spontaneous Ignition of Coal, 455; Ludwig Mond on Nickel-carbon Oxide and Metallic Nickel obtained therefrom, 455; Iron-carbon Oxide, 455; William Crookes, F.R.S., on the Electrical Evaporation of Metals and Alloys, 455; T. Turner on the Cause of the Red Blotches on the Surface of Brass Sheets, 455; A. P. Laurie on the Electromotive Forces of Various Alloys, 456: Prof. Roberts-Austen, F.R.S., on his Self-recording Pyrometer, 456; A. Vernon-Harcourt and F. W. Humphery on the Relation between the Composition of a Double Salt and the Composition and Temperature of the Liquid in which it is formed, 456; Report on the Isomeric Naphthalene Derivatives, 456; Profs. Rücker and Roberts-Austen on the Specific Heat of Basalt, 456; Prof. F. Clowes on an Apparatus for testing Safety-lamps, 456; Prof. C. M. Thompson on Rare Earths and New Elements, 456; Prof. Ramsay on the Liquids obtained by passing Excess of Hydrogen Sulphide into Solutions of certain Metals, 456: J. J. Sudborough on the Action of Nitrosyl Chloride on Unsaturated Carbon Compounds, 456; C. G. Moor on the Disposal of Sewage, 456; A. H. Allen on treating Glycerides with Alcoholic Potash, 456

Section C (*Geology*)—Prof. Boyd Dawkins, F.R.S., on the Channel Tunnel Boring and the Discovery of Coal, 479; W. Topley, F.R.S., on the Origin of Petroleum, 479; Sir Archibald Geikie, F.R.S., on the Discovery of the Olenellus Zone in the North-West Highlands of Scotland, 479; Sir Archibald Geikie, F.R.S., on the Recent Work of the Geological Survey in the Archæan Gneiss of the North-West Highlands of Scotland, 480; Sir R. S. Ball on the Cause of an Ice Age, 480; Rev. Dr. Crosskey on Distribution of Erratics in England and Wales, 480; Prof. Wright on the Ice Age in North America, 480; Report on the Elbolton Cave near Skipton, 480; Dr. Hicks on the Silurian and Devonian Rocks of Pembrokeshire, 480; Palæontological Papers, 481

Section D (*Biology*)—Opening Address by Francis Darwin, F.R.S., President of the Section, 407; Grenfell on the Structure of Diatoms, 481; Calderwood on Sea Fisheries, 481; J. T. Cunningham on the Reproduction of the Pilchard, 481; J. T. Cunningham on the Rate and Growth of Age of Sexual Maturity in Fish, 482; Prof. Herdman and J. A. Clubb on the Innervation of the Epipodial Processes of some Nudibranchiate Mollusca, 482; Prof. W. N. Parker on Respiration in Tadpoles, 482; Prof. Howes on the Classification of Fishes by their Reproductive Organs, 483; Prof. Howes on the Gills of Fishes, 483; Dr. Arthur Robinson on the Development of the Rat and the Mouse, 483; Prof. Marcus Hartog on Protoplasmic Rejuvenescence, 483; Francis Darwin, F.R.S., on the Artificial Production of Rhythm in Plants, 484

Section E (*Geography*)—Opening Address by E. G. Ravenstein, F.R.G.S., F.S.S., President of the Section, 423; Mrs. French Sheldon on East Africa, 508; Dr. Robert Felkin on Acclimatization, 508; Colonel Holdich on the Application of Indian Geographical Survey Methods to Africa, 508; H. T. Crook on our Ordnance Survey, 508; J. Scott Keltie on Geographical Education, 509

Section G (*Mechanical Science*)—G. Chatterton on Sewerage, 509; W. Key on Ventilation, 509; Sir Edward Reed on

the Proposed Channel Tubular Railway, 509; Prof. W Robinson on Petroleum Engines, 509; W. H. Preece, F.R.S., on the London and Paris Telephone, 510; Prof. G. Forbes on Electric Motors, 510; A. R. Bennett on Underground Parcels Delivery, 510; Major R. de Villamil on Screw Propellers, 510; Mr. Beaumont on Screw Propellers, 510
  Section H (*Anthropology*)—Opening Address by Prof. F. Max Müller, President of the Section, 428; Prof. R. K. Douglas on the Social and Religious Ideas of the Chinese, 510; Major J. W. Powell on Indian Languages, 511; the Marquis of Bute on the Language of Teneriffe, 511; Dr. E. B. Tylor, F.R.S., on Savage Religion, 511; S. E. Peal on the *Morong* of the Natives of Asam, 511; Dr. Garson on Human Remains found in Yorkshire, 511; Miss Buckland on the "Mountain Chant," 511; Dr. S. A. K. Strahan on Instinctive Criminality, 511; E. H. Man on Nicobar Pottery, 512
British Earthworms, Identification of Templeton's, Rev. Hilderic Friend, 273
British Institute of Preventive Medicine, 86, 97, 124, 301, 323
British Medical Association at Bournemouth, Meeting of, 161, 353
British Museum: Specimens of Asiatic Wild Sheep at, 40; British Museum in 1890, Decrease in Number of Visitors to, 280, 352; Additions to the Bird Department, 451; Systematic List of the Frederick E. Edwards Collection of British Oligocene and Eocene Mollusca in the, Richard Bullen Newton, 610
British Rule, South Africa from Arab Domination to, 564
Brocken Spectres in a London Fog, A. W. Clayden, 95
Brodie (Fredk. J.), the Recent Epidemic of Influenza, 283
Brooks (Prof. W. K.), the Oyster, a Popular Summary of a Scientific Study, 490
Brown (J. Allen), Technical Education in Middlesex, 65
Brown (J. S.), Bernardinite, is it a Mineral or a Fungus?, 310
Brunner (J. T., M.P.), Elected President of the Sunday Society, 135
Brünnow (Francis), Obituary Notice of, 449
Brunton (Dr. T. Lauder, F.R.S.): Supplement to the Textbook of Pharmacology, 41; on the Progress of Medicine, 327
Brussels Academy of Sciences, 24, 240, 312, 440, 560
Buchan (Dr.), Barometer at Ben Nevis Observatory in Relation to Wind, 167
Buckland (Miss), on the "Mountain Chant," 511
Buckmaster (Dr.), Leprosy Bacillus cultivated in Serum by, 161
Buckmaster (J. C.), County Councils and Technical Education, 588
Buchner (Dr.), Immunity, Natural and Acquired, 420
Buda-Pesth Academy of Sciences, Sir J. D. Hooker elected Foreign Member of, 257
Buller (Sir Walter, F.R.S.): a Remarkable Characteristic of the Wandering Albatross, 502; a New Species of Albatross, 502
Bulletin de la Société des Naturalistes de Moscou, 359
Buried Cities and Bible Countries, Geo. St. Clair, 540
Burmah and Assam, Botanical Survey in, Dr. King, 549
Burnham (S. W.), Double-star Observations, 283
Burrell (Edward J.), B.Sc. Exam. Lond. Univ. 1892, 565
Burton (F. M.), Bees and Honey-dew, 343
Burton (Sir R. F.), Funeral of, 161
Busch (Herr), Variations in Sunset Phenomena, 599
Bush Friends in Tasmania, Mrs. L. A. Meredith, 517
Bute (Marquis of), on the Language of Teneriffe, 511
Butter Export from New South Wales to England, 303

Cacao in Cultivation in Ceylon, Kinds of, Dr. Trimen, 185
Cahours (M.), on the Endowment of Research in France, 17
Cailletet (M.), Vapour-tension of Saturated Water-vapour at Critical Point, 119
Calculus, Differential and Integral, Prof. A. G. Greenhill, F.R.S., 170
Calcutta Indian Museum: Report of, 18; Completion of the Catalogue of the Mammals in the, 324
Calderwood on Sea Fisheries, 481
California: Severe Earthquake in, 206; Californian Trees and Flowers, 477; Hot Winds of, Lieutenant J. P. Finley, 512
Calleja (Dr. Camilo), General Physiology, 28
Cambridge: Philosophical Society, 96, 143, 191; Honorary Degrees on Scientific Men, 189; University Extension Students at, 205; the Study of the Classical Languages at, 628
Cameron (Donald), a Magnificent Meteor, 343
Campbell (Mr.), Record of a Journey in Northern Corea, 233
Canada, Geological Survey of, 114
Canadian Meteorological Service, Report for 1887 of, 136
Cape Colony, Meteorology of, 452
Carbon Dioxide, Production of Solid, Dr. Hassknecht, 42
Carbon Monoxide, Physiological Researches on, 392
Carbonic Acid Gas produced in Sugar-fermentation in Breweries, proposed Utilization of, 303
Carbonic Acid, New *Réseau* of Isotherms of, E. H. Amagat, 608
Cardiff, the Visit of the British Association to, 65, 204, 280, 371
Cardiogram, Displacements of Heart and, Dr. J. B. Haycraft, 167
Carpenter (Dr. Philip Herbert, F.R.S.), Obituary Notice of, 628
Cartography, Map-colouring and, Major J. W. Powell, 506
Carulla (Mr.), Curious Phenomena in Melting Bessemer Scraps, 579
Carus (Dr. Paul), the Soul of Man, 293
Carus-Wilson (Cecil), the Production of Musical Notes from Non-musical Sands, 322
Carus-Wilson (Prof. Charles A.): the Flying to Pieces of a Whirling Ring, 31; Instrument for Examining Strains in Bent Glass Beams, 187; Influence of Surface-loading on Flexure of Beams, 261
Cat, a Two-legged, Prof. Leon, 600
Catbird, Australian, Nest and Eggs of, A. J. North, 207
Caucasus, New Glaciers discovered in, 452
Cavern in Oregon, Discovery of Enormous Stalactite, 258
Caves, Stalactite, in Tasmania, Discovery of, Mr. Morton, 576
Cayeux (L.), Diffusion of Three Distinct Forms of Titanium-oxide in Cretaceous Strata of Northern France, 144
Cecil (Henry), Earthquake at Bournemouth, 614
Census, Results of the Recent, N. A. Humphreys, 161
Census, 1891, of the Parish of St. George, Hanover Square, Alleged Worthlessness of, 303
Census of India, 18
Cephalonia, the Climate of, Dr. Partsch, 326
Cerebral Localization, the Croonian Lectures on, Dr. David Ferrier, F.R.S., 292
Cetaceans in African Lakes, 124, 198
Ceylon, Kinds of Cacao in Cultivation in, Dr. Trimen, F.R.S., 185
Chabry (M.), Pressure which can be produced by Electrolytic Generation of Gas, M. Chabry, 577
Chamberlin (Prof. T. C.), Classification of the Glacial Pleistocene Deposits, 504
Chambers' Encyclopædia, Vol. VII., 173
Channel Tubular Railway, Sir Edward Reed on the Proposed, 509
Channel Tunnel Boring and the Discovery of Coal, Prof. Boyd Dawkins, F.R.S., 479
Chanute (O.), Chemical Methods of Protecting Railroad-ties against Decay, 476
Chapman (A. C.), Compounds of Dextrose with the Oxides of Nickel, 71
Charles (Dr. R. H.), Craniometry of Outcaste Tribes of Panjab, 576
Charpentier (A.), Oscillations of the Retina, 311
Charpy (Georges), Action of Nitric Acid upon Iron, 216
Chatin (A.), "Kammé," a New Species of Truffle, 512
Chatterton (G.), on Sewerage, 509
Chauveau (A.): on Blending of Separate Chromatic Sensations perceived by each of Two Eyes, 488; Colour-Sensation excited in One Eye by Coloured Light Illuminating Retina of other, 536
Cheese, Digestibility of Different Kinds of, Herr Klenze, 325
Cheeseman (T. F.), the Basking Shark in New Zealand Waters, 576
Chemistry: Crystallization of Ammonium Sulphovanadate, Drs. Krüss and Ohnmais, 19; Silicon Chlorotribromide, 19; Compounds formed by Mercuric Chloride, 48; a System of Inorganic Chemistry, William Ramsay, F.R.S., 50; Chemical Society, 71, 118, 215, 287; Citraconfluorescein, J. T. Hewitt, 71; Ethylic Thiacetacetate, Dr. C. T. Sprague, 71; the Function of Chlorine in Acid Chlorides, Prof. H. E.

Armstrong, F.R.S., 71; the Action of Nitric Acid on the Lignocelluloses, C. F. Cross and C. A. Bevan, 71; Studies on the Formation of Substitution Derivatives, H. Gordon, 71; Compounds of Dextrose with the Oxides of Nickel, A. C. Chapman, 71; the Gravivolumeter, F. R. Japp, F.R.S., 72; the Action of Acetic Acid on Phenylthiocarbimide, J. C. Cain and Dr. J. B. Cohen, 72; Action of Aluminium Chloride on Benzinoid Acid Chlorides, R. E. Hughes, 72; Sulphides of the Organic Radicles, 89; Elementary Chemistry for Beginners, W. Jerome Harrison, 102; Discovery of Brilliant Purple Gold and Aluminium Alloy, Prof. Roberts-Austen, 111; Synthetization of Indigo-carmine, Dr. Heymann, 114; Action of Alkalies on Nitro-compounds of Paraffin Series, W. R. Dunstan and T. S. Dymond, 118; New Addition Compound of Thiocarbamide, J. E. Reynolds, F.R.S., 118; Action of Acetic Anhydrides on Substituted Thiocarbamides, and an Improved Method of preparing Aromatic Mustard Oils, E. A. Werner, 118; Decomposition of Silver Chloride by Light, A. Richardson, 118; the Addition of Alcohol Elements to Ethereal Salts of Unsaturated Acids, T. Purdie and W. Marshall, 118; Azo-derivatives of β-Naphthylamine, R. Meldola, F.R.S., and F. Hughes, 118; Method for Estimation of Nitrates, G. McGowan, 118; New Benzylic Derivatives of Thiocarbamide, A. E. Dixon, 118; the Sub-chlorides of Silver, M. Guntz, 120; Electrolysis of Fused Salts of Boron and Silicon, Adolphe Minet, 120; Two New Crystalline Compounds of Platinic Chloride with Hydrochloric Acid, Léon Pigeon, 120; Stas's Work in Atomic Determination, 134; Troilite, Meteoritic Crystallized Monosulphide of Iron, Dr. Richard Lorenz, 137; Chemistry in Space, Prof. T. H. van 't Hoff, translated by J. E. Marsh, 150; the New Peroxide of Sulphur, Prof. Traube, 163; Dr. Gustavus Hinrichs on the Fusing and Boiling Points of Compounds, 174: Action of Fluorine upon Phosphorus Trifluoride, M. Moissan, 186; Nickel-Carbon-Oxide, Ludwig Mond, F.R.S., 187; Calorimetric Researches on Humic Acid derived from Sugar, MM. Berthelot and André, 144; Determination of Molecular Weights of Critical Point, P. A. Guye, 144; Research on Separation of Metals from Platinum, A. Joly and E. Leidié, 144; Specific Heats of some Solutions, W. Timofeiew, 144; Solubility of Mixed Crystals of Isomorphous Substances, Dr. B. Roozeboom, 144; Blue Silver, M. C. Lea, 189; Bromo-Derivatives of Betanaphthol, H. E. Armstrong and E. C. Rossiter, 190; Action of Nitric Acid on Naphthol Derivatives, the Formation of Nitro-Keto-Compounds, H. E. Armstrong and E. C. Rossiter, 190; New Method of preparing Nitro-Derivatives, and Use of Nitrogen Dioxide as a Nitrating Agent, H. E. Armstrong and E. C. Rossiter, 190; Nitrification applied to Agriculture, R. Warington, 190; Iron-Carbonyl and Nickel-Carbonyl, M. Berthelot, 192; Cotton-bleaching by Oxygenated Water and Calcined Magnesia, M. Prudhomme, 192; Application of Measure of Rotatory Power to Determination of Compounds of Aqueous Solutions of Mannite with Acid Molybdates of Soda and Ammonium, 192; Proceedings of the Association of Official Agricultural Chemists, 1890, 317; the Preparation of Iron-Carbonyl and several New Reactions of Nickel-Carbonyl, M. Berthelot, 208; Molecular Refraction and Dispersion of various Substances in Solution, Dr. J. H. Gladstone, F.R.S., 215; Nature of Solutions as elucidated by Study of Densities, &c., of Solutions of Calcium Chloride, S. U. Pickering, 215; Note on a Recent Criticism by Mr. Lupton of Conclusions drawn from a Study of Sulphuric Acid Solutions, S. U. Pickering, 215; Volatile Platinum Compounds, W. Pullinger, 215; Researches on Osmium, Osmiamic Acids and Osmiamates, A. Joly, 216; Action of Nitric Acid upon Iron, H. Gautier and Georges Charpy, 216; the Cryogen, an Apparatus for quickly Lowering Temperature by Expansion of Liquid Carbonic Acid, M. Ducretet, 232; Microcidine, a New Antiseptic, Prof. Berlioz, 232; a Volatile Compound of Iron and Carbonic Oxide, Ludwig Mond and F. Quincke, 234; Study of Planté Cell from Chemical Point of View, I., G. H. Robertson, 236; II., H. E. Armstrong, F.R.S., and G. H. Robertson, 237; on Persulphates, M. Edinburgh University, Summer Graduation Ceremony, 323
Education: Technical, and County Councils, 324; Sir T. H. Farrer, 6; J. C. Buckmaster, 588; the Technical Education of Girls, 185; National Association for the Promotion of Technical, 231; Lord Hartington on Technical Education, 234; Technical Education in the South-Eastern Counties of England, 303; Technical Education for Farmers, Farriers, and Engine Drivers, John L. Winter, 320; the City and Guilds of London Institute and Instruction in Woodwork in Public Elementary Schools, 327; the Progress of Technical Education, 351; New Physics and Electrical Engineering Department at Manchester Technical School, 475; Technical Education in Essex, 548; in Scotland, 549; Advertisements for Instructors, 565; Alterations in the Science and Art Directory, 40; University Extension Scheme, 40; Eighteen Years of University Extension, 52; Education in India, 67, 88; Secondary Education in Scotland, 161; Educational Aspects of Free Education, 169; Technical Education in Agriculture, Dr. W. Fream, 137; University of Oxford and Agricultural Education, 183; Hygienic Advantage of Erect as Compared with Slanting Writing, Dr. Lorenz, 325; the Kindergarten System in New York, 502; Increased Accommodation for Scientific Education at Oxford, 111; the Scientific Measurement of Children with Respect to Education, Rev. H. A. Soames, 114; Scientific, Appointments to 1851 Exhibition Science Scholarships for 1891, 258, 351; Les Sciences Naturelles et l'Éducation, Prof. T. H. Huxley, F.R.S., 272; Existing Schools of Science and Art, Oliver S. Dawson, 547; Proposed Informal Congress at Edinburgh on Scottish Higher Education, 258; Annual Report of Oxford University Extension Delegates on Secondary Education, 451; Education and Heredity, J. M. Guyau, 292
Edwards (Frederick E.) Collection of British Oligocene and Eocene Mollusca in the British Museum, Systematic List of, Richard Bullen Newton, 610
Eginitis (D.), Observation of Passage of Mercury across Sun's Disk, May 9, 1891, 119
Egypt: Locusts in, 40; the Dog in Ancient Egypt, M. Maspero, 207; the Preservation of Ancient Monuments in, 281; the Engineering Importance of Dongola, 301; the Projected Storage Reservoir, 548; Discovery of Three Colossal Statues at Aboukir, 575; Exploration in, Flinders Petrie, 630; Egyptian Irrigation, 145; Sir Colin Moncrieff on, 151
Ehrlich (Prof.), Koch's Present Views regarding Tuberculin, 398
Ehrlich (Dr.), Immunity, Natural and Acquired, 422
Elbolton Cave near Skipton, B.A. Report on, 480
Electricity: Hertz's Experiments, 12, 31; Electricity in the Physical Department at Bangor University College, 18; Intensity Coils, how made and how used, by "Dyer," 28; Production of Solid Carbon Dioxide, Dr. Haussknecht, 42; Earth Currents, the Electric Railway and the Royal Observatory, William Ellis, 127; the Theory of Electro-dynamics, J. Larmor, 139; Blakesley's Method of Measuring Power in Transformers, Prof. Perry, F.R.S., 142; New Model of Copper Oxide Batteries, F. de Lalande, 144; Quadrant Electrometers, W. E. Ayrton, F.R.S., J. Perry, F.R.S., and W. E. Sumpner, 166; Pocket Electrometers, C. V. Boys, F.R.S., 262; Dielectric Properties of Mica at High Temperatures, E. Bouty, 168; Discharge without Electrodes through Gases, Prof. J. J. Thomson, F.R.S., 187; Experiments on Liquid Electrodes in Vacuum Tubes, C. Chree, 191; Electrical Evaporation, Wm. Crookes, F.R.S., 212; Electrolysis of Barium Chloride, C. Limb, 216; the Formation of Salts, a Contribution to the History of Electrolysis, H. E. Armstrong, F.R.S., 287; Papers on Electrolysis at the Meeting of the British Association, 454; Conversazione of the Institution of Electrical Engineers, 231; Study of Planté Cell, from Chemical Point of View, I., G. H. Robertson, 236; II., H. E. Armstrong, F.R.S., and G. H. Robertson, 237; Alternate Current and Potential Difference, Analogies in Methods of Measuring Power, Prof. Ayrton and Dr. Sumpner, 237; Experiments with Leyden Jars, Prof. Oliver J. Lodge, F.R.S., 238; Contributions to the Study of Atmospheric, Ch. André, 240; Magnetic Anomalies, Alfonso Sella, 249; Construction of Non-inductive Resistances, Prof. W. E. Ayrton, F.R.S., and T. Mather, 261; the Observation of Atmospheric, Herren Elster and Geitel, 281; Prof. Poincaré on Maxwell's Electro-magnetic Theories, Prof. A. Gray, 296; Electric Resistance of Cobalt, Prof. Knott, 311; the Relative Cost of Electricity in London and Elsewhere, M. Haubtmann, 324; the Origin of the New Electric Photophone, 325; Messrs. Staite and Petrie's New Electrical Light, 327; Proposal by Sir Edward Watkin to place Electric Light on Snowdon, 352; Electric Light Fitting, a Handbook for Working Electrical Engineers, John W. Urquhart, 586; the Report of the Board of Trade Committee on Electrical Standards, 417; Electrical Standards, 434; an Introduction to the Mathematical Theory of Electricity and Magnetism, W. T. A. Emtage, 443; Electrical Exhibition, Crystal Palace, 450, 597; Proposed International Conference of Electricians at Chicago Exhibition, 450, 575; International Electro-Technical Congress, 450; Electric Observations on Sonnblick, Herren Elster and Geitel's, 452; Prof. D. E. Jones on Electric Waves in Wires, 454; A. P. Laurie on the Electromotive Forces of Various Alloys, 455; Dampening of Oscillations in Iron Wire, John Trowbridge, 463; Frankfort International Electrical Exhibition, 494, 521, 542, 615; Prof. G. Forbes on Electric Motors, 510; Electric Transmission of Power, Joseph J. Murphy, 590; Mr. C. E. Kelway's Apparatus for Marine and General Electrical Signalling, 575
Elkin (Dr.), Observatory of Yale University, 283
Ellacott (Captain Wm.), a Comet observed from Sunrise to Noon, 82
Ellery (R. L. J., F.R.S.), Earthquake Shocks in Italy and Australia, 272
Elliott (Edwin Bailey), proposed Fellow of the Royal Society, 15
Ellis (William): Earth Currents, the Electric Railway, and the Royal Observatory, 127; Comparison of Thermometrical Observations in Stevenson Screen with same on Revolving Stand at Greenwich Observatory, 239

Elster (Herr), the Observation of Atmospheric Electricity, 281
Elster and Geitel (Herren), Electric Observations on Sonnblick, 452
Embryology: Pycnogonids or Sea-Spiders, 49
Emin (Pasha), Ornithology of Lake Victoria Nyanza, 87
Emmerich (Prof.), Immunity, Natural and Acquired, 421
Emmons (S. F.), a Geological Excursion in America, 182
Emtage (W. T. A.), an Introduction to the Mathematical Theory of Electricity and Magnetism, 443
Encke's Comet, *c* 1891, 355; Dr. Backlund, 438
Endowment of Research in France, MM. Cahours and Janssen, 17
Energy, on some Test Cases for the Maxwell-Holtzmann Doctrine regarding Distribution of, Sir William Thomson, P.R.S., 355
Engineer Attachés to Austrian Embassies, Proposed, 575
Engineering: Marine Engine Trials, 20; Achievements in, L. F. Vernon-Harcourt, 147; Engineering Importance of Dongola, the, Mr. Willcocks, 301; Government Timber Tests, B. E. Fermor, 471; Electrical Engineering, 494, 521, 542; the Projected Egyptian Storage Reservoir, 548; Electric Light Fitting, a Hand-book for Working Electrical Engineers, John W. Urquhart, 586; Conversazione of the Institution of Electrical Engineers, 231; Institution of Mechanical Engineers, 332
Engrais Chimiques, Les, Georges Ville, 517
Entomology: the Fossil Insects of North America, with Notes on some European Species, Samuel H. Scudder, R. Lydekker, 1; the Locust in India, 18; Entomological Society, 95, 143, 262, 488; a New Sponge Worm Parasite, Prof. W. B. Spencer, 120; the Blow-fly, B. Thompson Lowne, 123; Redevelopment of Lost Limbs in Insects, John Watson, 163: the Insect House in the Zoological Gardens, 163, 198; Supernumerary Legs and Antennæ in Beetles, W. Bateson, 188; Rearrangement of the South African Museum Collection of Lepidoptera by R. Trimen, 207; the United States Entomological Commission, Dr. Alpheus S. Packard, 217; Luminous Insects in Australian Bush, Henry Deane, 233; Ant-imitating Bug, Mr. Wroughton, 262; Insect-flight Studied by Photochronography, M. Marey, 264; Coleoptera of Yarkand, 318; New Species of Russian Trap Spider, W. A. Wagner, 359; the Song of the Cicada, 437; Agricultural Entomology, Resignation of Miss Ormerod, 451, 528; Mimicry in Spiders, E. Heckel, 451; Some Difficulties in the Life of Aquatic Insects, Prof. L. C. Miall, 457; Insects and Flowers, G. F. Scott-Elliott, 488; *Hemisaga hastata* and *Danais chrysippus* (Butterfly), W. L. Distant, 488; *Scoria dealbata*, H. Goss, 488; Dragon-flies *v.* Mosquitoes, 491; Orange Disease in Cyprus, A. E. Shipley, 528; Remarkable Instance of Frugality in Bees, W. H. Harris, 550; W. M. Maskell on the Coccidæ, 550; a New South Wales Beetle (fam. Curculionidæ) as an Example of Protective Coloration, Mr. Froggatt, 576
Eozoon, the Origin of, 308
Epidemics: Measures adopted for the Prevention of Infectious Diseases, and their Relation to our Knowledge of, Dr. Lewis Sambon, 486
Epilobium, the Species of, occurring North of Mexico, Dr. Trelease, 196
Erratics, the Distribution of, in England and Wales, Rev. Dr. Crosskey, 480
Espin (Rev. Dr. T. E.): Photo-Stellar Spectra, 133; Two New Variable Stars, 578
Essex County Council and Technical Education, 324, 548
Ether, Clock for pointing out the Direction of the Earth's Orbital Motions in, Prof. Oliver J. Lodge, F.R.S., 238
Ether of Space, on the Functions and Nature of the, Prof. F. E. Nipher, 471
Ethers, the Rate of Formation of Compound, N. Menschutkin, 312
Ethnology: of Sumatra, 68; Races and Peoples, Lectures on the Science of Ethnography, Dr. Daniel G. Brinton, 124; American Ethnological Expedition to Labrador, 185; Manners and Customs of Shan States, W. R. Hillier, 137; the Amerrique Indians of Nicaragua, J. Crawford, 502; the Aborigines of the Malay Peninsula, 600
Ethyl Oxide, an Attempt to determine the Adiabatic Relations of, Prof. W. Ramsay, F.R.S., and E. P. Perman, 22
Eucalypts, the Classification of, 41
Eucalyptus Branches, Green, as a Disinfectant, Baron von Mueller, 353; J. Brendon Curgenven, 445
Euclid, Books I.–II, Rider Papers on, Rupert Deakin, 76
European Botany, Vol. I., K. Richter, J. G. Baker, F.R.S., 100
European Weather Charts, Captain C. H. Seemann on, 41
Evaporating Power of a Climate, Determination of, Dr. Ule, 137
Evaporation, Electrical, William Crookes, F.R.S., 212
Evaporation, Water, in Sun and in Shade, Signor Batelli's Experiments on, 136
Everett (Prof., F.R.S.), Illustrations of C.G.S. System of Units, with Tables of Physical Constants, Prof. John Perry, F.R.S., 489
Evolution of Algebra, on the, Prof. E. W. Hyde, 470
Evolution, the Classification of the Tunicata in Relation to, Prof. W. A. Herdman, 130
Evolution, Cosmical, a New Theory of the Mechanism of Nature, Evan McLennan, 342
Evolutionary Castigation, Rev. John Gerard, S.J., Prof. R. Meldola, F.R.S., 441
Ewing (Prof. J. A., F.R.S.), the Molecular Process in Magnetic Induction, 566
Exhibition, the Coming Chicago, 258; and the McKinley Bill, 351; Mines and Mining Department at Chicago, 476; British Electrical Display at the, 575
Exhibition, Contemplated Victorian, 352
Exhibition, Crystal Palace Electrical, 450, 597
Exhibition of 1851 Science Scholarships, 351
Exhibition of Photographic Society of Great Britain, 231
Expedition Afoot to the North Pole, Lieutenant Peary's Projected Botanical, 231
Expedition, Baron Nordenskiöld's Proposed Antarctic, 231
Expedition, the Heilprin Greenland, the Accident to and Position of Lieutenant Peary, 475
Expedition to Labrador, American Ethnological, 185
Expedition to Liberia by O. F. Cook, Projected Natural History, 548
Expedition to Pahang, Straits Government Scientific, 112
Expedition, Pilcomayo, J. Graham-Kerr's, 135
Expedition, Scientific, for Investigation of South Maryland, 208
Expeditions to the Chin Hills and Bhamo Country, Projected, 550
Experimental Physics: Liquids and Gases, Prof. W. Ramsay, F.R.S., 274
Experimental Researches on Mechanical Flight, Prof. S. P. Langley, 277

Face, the Growth of the, Prof. G. M. West, 325
Fairyland Tales of Science, Prof. J. G. McPherson, 5
Faraday Centenary, Lord Rayleigh, F.R.S., 178
Faraday (Michael), a Souvenir of, 230
Farrer (Sir T. H., Bart.), County Councils and Technical Education, 6
Fatio (Victor), Faune des Vertébrés de la Suisse, Dr. Albert Günther, 269
Faye's (M.) Theory of Cyclones, Henry F. Blanford, F.R.S., 348
Fayrer (Sir Joseph, F.S.A.): Elected Member of the Royal Italian Society of Hygiene, 323; Elected Associate of Paris Academy of Medicine, 351; Address in the Section of Preventive Medicine at the Congress of Hygiene, 363
Fecundation, Morphological Nature of Principle of, Léon Guignard, 168
Federated Institution of Mining Engineers, 500
Felkin (Dr. Robert), on Acclimatization, 508
Fermor (B. E.), on Government Timber Tests, 471
Ferns, Hand-book of the, of Kaffraria, T. R. Sim, J. G. Baker, F.R.S., 75
Ferrel (Prof. Wm.): Death of, 500; Obituary Notice of, 527
Ferrier (Dr. David, F.R.S.): the Croonian Lectures on Cerebral Localization, 292; Presentation of Cameron Prize to, 351
Festing (General, F.R.S.), Greater Sensitiveness of Eye to Different Colours, Apparatus to show the, 187
Ficheur (M.), the Eocene Formation of Algeria, 264
Field Naturalists' Club of Victoria, Excursion to Kent Islands, 476
Finger Marks, Method of Indexing, Francis Galton, F.R.S., 141
Finger Prints as a Means of Identification, Francis Galton, F.R.S., 187

Finkelnburg (Dr.), on the Influence of Soil on Consumption, 370
Fire-Prevention: the Society of Arts Fothergill Gold Medal for, 135; 1000 Lire Gold Medal offered by Bologna Academy for Memoir on best Means of, 303
Firs and Pines of Japan, Dr. Maxwell T. Masters, F.R.S., 339
Fischer (H.), Development of Liver of Nudibranchiates, 144
Fish: some Remarkable Catches of, 19; the Destruction of, by Frost, F. F. Payne, 31; Fossil Fish of the Scandinavian Chalk, 117; Faune des Vertébrés de la Suisse, Victor Fatio, Dr. Albert Günther, F.R.S., 269; J. T. Cunningham on the Reproduction of the Pilchard, 481; J. T. Cunningham on the Rate and Growth of Age of Sexual Maturity in Fish, 482; Prof. Howes on the Classification of Fishes by their Reproductive Organs, 483; Prof. Howes on the Gills of Fishes, 483; United States Fish Commission Reports, 562; Oyster Fisheries, Mr. Fryer, 233; Fish caught in the Cruise of the *Fingal*, 1890, off West Coast of Ireland, E. W. L. Holt, 282; Calderwood on Sea Fisheries, 481; the Baltimore Fishing School and Irish Fisheries, 549
Fisher (Prof. W. R.), Forestry in North America, 60
Fizeau (M.): Influence that Aberration of Light may Exercise on Spectroscopic Observations of Solar Prominences, 488; Influence of Aberration upon Observations of Solar Prominences, 530
Flame, Optical Proof of Existence of Suspended Matter in, Prof. Stokes, F.R.S., 263
Flammarion (C.), Apparent Total Disappearance of Jupiter's Satellites, 311
Flesh, Organic Bases in the Juice of, G. S. Johnson, 117
Fletcher (Thomas), Rain Gauges, 371
Flight, Experimental Researches on Mechanical, Prof. S. P. Langley, 277
Flora, Alpine, T. D. A. Cockerell, 6; J. Innes Rogers, 6
Flora of European Russia, Geo-botanical Notes on, D. I. Litvinoff, 359
Flora of the Malayan Peninsula, Materials for a, Geo. King, F.R.S., 492
Florida, Rain Making in, in the Fifties, 521
Flower (Prof. W. H., F.R.S.): an "International Society," 7; and Richard Lydekker, Mammals Living and Extinct, Prof. E. Ray Lankester, F.R.S., 121; Oxford University Museum, 619
Flowers, our Country's, W. J. Gordon, 247
Fluorine, Action of, on Phosphorus Trifluoride, M. Moissan, 186, 333, 622; A. E. Tutton, 333
Fluorine, Further Researches upon the Element, A. E. Tutton, 622
Foerster (Dr.), Volatile Carbonyl Compounds of Platinum, 530
Fog, a Method of Counting Water-Particles in, John Aitken, 119
Folk-lore Congress, International, the, 527
Folk-lore of the Hungarian Gypsies, Dr. H. von Wlislocki, 630
Folk-lore, the Melanesians, Studies in their Anthropology and, Dr. R. H. Codrington, 613
Food, Copepoda as an Article of, Prof. W. A. Herdman, 273
Food Physiology, William Durham, 540
Forbes (Prof. G.), on Electric Motors, 510
Force and Determinism: Evan McLennan, 198; Prof. Oliver J. Lodge, F.R.S., 198, 272; Prof. C. Lloyd Morgan, 249, 319; Edward T. Dixon, 249, 319; Rev. T. Travers Sherlock, 320; D. Wetterhan, 320
Force and Motion, the Laws of, John Harris, 443
Forestry in India, 436
Forestry in North America, Prof. W. R. Fisher, 60
Forestry, the Teaching of, William Schlich, Sir D. Brandis, F.R.S., 265
Forestry, on Government Timber Tests, B. E. Fermor, 471
Forests and Air-Temperature, 68
Forty Years in a Moorland Parish, Rev. J. C. Atkinson, 122
Fossil Fish of the Scandinavian Chalk, 117
Fossil Insects of North America, with Notes on some European Species, Samuel H. Scudder, R. Lydekker, 1
Fossils, *Protopirata centrodon*, H. Trautschold, 359
Foster (Prof. G. Carey, F.R.S.), the Proposed Albert University, 223
Fourteenth Century Weather Record, 538
Fox (Dr. L. W.), Rarity of Colour-Blindness in Savage Races, 477
Fox's Head for Country, the, J. Harting, 452
France: Endowment of Research in, MM. Cahours and Janssen, 17; French Accent, Dr. Pringsheim, 67; French Meteorological Society, 112; New Natural History Stations in France, 135; French Academy's 20,000 franc Prize voted to Elisée Reclus, 161; the Proposed Law on Universities, 185; French Association for the Advancement of Science, 280, 499, 598; Lighting in France, the Increase in the Consumption of Gas, Electricity, and Petroleum, during the Last Decade, 282; the Protection of Prehistoric Monuments in, 232; the Destruction of Small Birds in, 390
Frank (Dr. J.), a Case of Periodical Skin-shedding, 477
Frankfort, Acclimatization of Japanese Lacquer-tree at, Prof. Rein, 500
Frankfort International Electrical Exhibition, 494, 521, 542; some Notes on the, 615
Frankland (Percy Faraday): proposed Fellow of the Royal Society, 15; Manuel Pratique d'Analyse Bactériologique des Eaux, Dr. Miquel, 513
Fream (Dr. W.), Technical Education in Agriculture, 137
Freeman (Dr. J. P. Williams), Importance of more actively enforcing Ventilation, 487
French (C.), the Insectivorous Birds of Victoria, 162
Friend (Rev. Hilderic), Identification of Templeton's British Earthworms, 273
Froggatt (Mr.), a New South Wales Beetle (fam. Curculionidæ) as an Example of Protective Coloration, 576
Frost Phenomenon, Unusual, A. H. White, 519
Fryer (Mr.), Oyster Disease and its Remedies, 233
Fürstlich Jablonowsky Gesellschaft, 325; Astronomical Prize offered by, 325
Fusing and Boiling Points of Compounds, Dr. Gustavus Hinrichs, 174

Galton (Sir Douglas, F.R.S.), Address at the Congress of Hygiene, 362
Galton (Francis, F.R.S.): Method of Indexing Finger-marks, 141; Finger-prints as a Means of Identification, 187; Meteorological Phenomenon, 294
Gardiner (Walter, F.R.S.), Water taken up by Plants, Phenomena associated with the Absorption and Flow of, 188
Garnier (Jules), Transport of Metallic Iron and Nickel by Carbon Monoxide, 336
Garson (Dr.), on Human Remains found in Yorkshire, 511
Gas Jets under Pressure, Combustion of, R. W. Wood, 189
Gas Mixtures, the Slow Combustion of Explosive, Krause and Meyer, 354
Gases in various Geological Phenomena, Probable *Rôle* of, M. Daubrée, 360
Gases, on Double Lines in the Spectra of, Dr. Johnstone Stoney, F.R.S., 454
Gases, the Foundation of the Kinetic Theory of, V., Prof. Chrystal, 310
Gases, Liquids and, Prof. W. Ramsay, F.R.S., 274
Gautier (Henry), Action of Nitric Acid upon Iron, 216
Geikie (Sir Archibald, F.R.S.): on the Discovery of the *Olenellus* Zone in the North-West Highlands of Scotland, 479; on the Recent Work of the Geological Survey in the Archæan Gneiss of the North-West Highlands of Scotland, 480
Geitel (Herr), the Observation of Atmospheric Electricity, 281
Geitel and Elster's (Herren) Electric Observations on Sonnblick, 452
Gem Thief, Capture at Vienna of a supposed, 598
Genoa, projected International Botanical Congress at, 598
Geo-botanical Notes on Flora of European Russia, D. I. Litvinoff, 359
Geography: Geographical Society, *see* Royal; Major Claude M. Macdonald on the Benué and the Kibbé, 46; the Miranzai Expedition, 65; Alexander McPhee on the Exploration of Central Australia, 67; Physical Geography and Geology of North Syria, Prof. Edward Hull, F.R.S., 99; Mr. J. Graham-Kerr's Pilcomayo Expedition, 135; Major Hobday's Explorations on the Upper Irrawaddy, 137; Across East African Glaciers, an Account of the First Ascent of Kilimanjaro, Dr. Hans Meyer, 149; Contemplated Geographical Society at Liverpool, 161; Physical Geography of the Clyde Sea Area, Dr. H. R. Mill, 167; Dr. John Murray, 232; the Karwendel Alps, A. Rothpletz, 221; the History of Commerce in England, H. de B. Gibbins, 222; the Northern Limits of the Black-Earth Steppe Region of East Russia, Korzchinsky, 326; Record of a Journey in Northern Corea, Mr. Campbell, 233; the Business of Travel, W. Fraser Rae,

247; the Yoruba Country, West Africa, Alvan Millson, 209; a Journey in Gazaland, South-East Africa, Denis Doyle, 209; Proofs that Asia and America have been Recently Connected, Emile Blanchard, 335; the International Geographical Congress at Berne, 355; Prince of Monaco's New Yacht for Study of the Sea, 359; the Field of Geography, E. G. Ravenstein, 423; Exploration of Greenland, 436; the Nunivak Islanders, Ivan Petroff, 477; Mrs. French Sheldon on East Africa, 508; Dr. Robert Felkin on Acclimatization, 508; Colonel Holdich on the Application of Indian Geographical Survey Methods to Africa, 508; H. T. Crook on our Ordnance Survey, 508; J. Scott Keltie on Geographical Education, 509; Russian Geographical Society's Medal Awards, 598; Mr. Joseph Thomson's Explorations in South Africa, 598; Prof. Russell's Excursion to Alaska, 629

Geology: the Crystalline Rocks of the Lizard District, Prof. T. G. Bonney, F.R.S., and General C. A. McMahon, 22; Geological Society, 22, 94, 143, 191, 240; Aids in Practical Geology, Prof. Grenville A. J. Cole, Prof. A. H. Green, F.R.S., 25; an Introduction to the Study of Petrology, Dr. Frederick H. Hatch, Prof. A. H. Green, F.R.S., 25; the Tin Resources of Tenasserim, 40; Notice of Mathurin Roussault, 68; the Eocene and Oligocene Beds of the Paris Basin, 88; Rhætic Section at Pylle Hill, Bristol, E. Wilson, 94; a Microscopic Study of the Inferior Oolite of the Cotteswold Hills, Edward Wethered, 95; Geology and Physical Geography of North Syria, Prof. Edward Hull, F.R.S., 99; Geologie, Principes, H. Hermite, 102; Geological Survey of Canada, 114; Relative Age of Quaternary Stratum of Mont Dol, M. Sirodot, 119; Lower Jaws of Procoptodon, R. Lydekker, 143; Recently Exposed Sections in Glacial Deposits at Hendon, H. Hicks, F.R.S., 143; Diffusion of Three Distinct Forms of Titanium Oxide in Cretaceous Strata of Northern France, Dr. B. Roozeboom, 144; Geologists' Association, a Record of Excursions made between 1860 and 1890, edited by Thomas Vincent Holmes and C. Davies Sherborn, 149; *Parka decipiens*, 165; Geology of the Country around Liverpool, G. H. Morton, Prof. W. Boyd Dawkins, F.R.S., 172; a Geological Excursion in America, S. F. Emmons, 182; the International Geological Excursion in America, 629; Captain Dutton and Geology in America, 183; Post-glacial History of Hudson River Valley, F. J. H. Merrill, 189; Post-Tertiary Marine Deposits on South Coast of England, Alfred Bell, 191; the Glacial Epoch Relics at Kelley Island, Ohio, 207; Traces of an Inter-glacial Period in Middle Russia, N. Krischtafovitch, 232; Wells in West Suffolk Boulder-Clay, Rev. Edwin Hill, 240; Inverness Earthquakes of 1890, C. Davison, 240; the Eocene Formation of Algeria, MM. Pomel and Ficheur, 264; Geological Map of Monte Somma and Vesuvius, H. J. Johnston-Lavis, 271; the Fossil Echinoidea of Malta, and their Evidence on the Correlation of the Maltese Rocks, J. W. Gregory, 311; Hand-book of the London Geological Field Class, 317; Probable *Rôle* of Gases in various Geological Phenomena, M. Daubrée, 360; Death of Prof. Martin Duncan, F.R.S., 387; Pleistocene Fluvial Planes of Western Pennsylvania, Frank Leverett, 463; on the Relations of the Chemung and Catskill on the Eastern Side of the Appalachian Basin, Prof. J. J. Stevenson, 471; a Preliminary Report of Observations at the Deep Well, Wheeling, W. Va., William Hallock, 472; Prof. Boyd Dawkins, F.R.S., on the Channel Tunnel Boring and the Discovery of Coal, 469; W. Topley, F.R.S., on the Origin of Petroleum, 479; Sir Archibald Geikie, F.R.S., on the Discovery of the Olenellus Zone in the North-West Highlands of Scotland, 479; Sir Archibald Geikie, F.R.S., on the Recent Work of the Geological Survey in the Archæan Gneiss of the North-West Highlands of Scotland, 480; Sir R. S. Ball on the Cause of an Ice Age, 480; Rev. Dr. Crosskey on the Distribution of Erratics in England and Wales, 480; Prof. Wright on the Ice Age in North America, 480; Report on the Elbolton Cave near Skipton, 480; Dr. Hicks on the Silurian and Devonian Rocks of Pembrokeshire, 480; Palæontological Papers, 481; the International Geological Congress—Washington Meeting, 504; Prof. Joseph Le Conte, 504; Prof. T. C. Chamberlin, Prof. T. McK. Hughes, and Mr. McGee on Classification of the Glacial Deposits, 504; Mr. Gilbert on the Correlation of Geological Formations, 505; Prof. E. W. Hilgard on the Importance of the Abundance or Scarcity of Species in the Correlation of Strata, 506; Major J. W. Powell on Map-colouring and Cartography, 506; Antiquity of the Last Glacial Period, N. S. Shaler, 529; Geological Formations exposed in Bridgwater Railway Cuttings through Polden Hills, J. F. M. Clarke, 530; the Ice Age in North America, G. F. Wright, Prof. T. G. Bonney, F.R.S., 537; South Italian Volcanoes, Dr. Johnston-Lavis, 539; the Rapakiwi, J. J. Sederholm, 548; Geology of the Maltese Islands, J. H. Cooke, 550; Geological Society of America, 601; Obituary Notice of Prof. Alexander Winchell, 601; Sur l'Existence du Dinotherium en Roumanie, Prof. Gregoire Stefanescu, 602; Systematic List of Frederick E. Edwards Collection of British Oligocene and Eocene Mollusca in the British Museum (Natural History), Richard Bullen Newton, 610; Memorials of John Gunn, being some Account of the Cromer Forest Bed and its Fossil Mammalia, 612

Geometry of Conics, Dr. Taylor's Elementary, 517

Geometry of Position, R. H. Graham, Alex. Larmor, 195

Gerard (Rev. John, S. J.), Science or Romance, Prof. R. Meldola, F.R.S., 441

German Naval Observatory, Hamburg, Catalogue of the Library of, 318

German Ornithological Society, Annual Meeting, 39

German Society for the Encouragement of Industry, Prizes, 66

Germany, the Heavy November Rains and Floods in, Prof. Hellmann, 206

Gernez (D.), Application of Measure of Rotatory Power to Determination of Compounds of Aqueous Solutions of Mannite with Acid Molybdates of Soda and Ammonium, 192

Ghizeh Museum, Mummies, Papyri, &c., at, 66

Gibbins (H. de B.), the History of Commerce in England, 222

Gibbs (Prof. J. Willard), Quaternions and the Ausdehnungslehre, 79

Gibert (Dr.), on Diphtheria, 369

Giglioli (Dr. Italo), Rain-Making, 590

Gilbert (Mr.), Correlation of Geological Formations, 505

Gilchrist (Percy G.), Proposed Fellow of the Royal Society, 15

Gill (C. Haughton), on Diatoms, 23

Gill (Dr. David, F.R.S.), an Astronomer's Work in a Modern Observatory, 603

Giraffe and its Allies, 524

Girls, the Technical Education of, 185

Glacial Epoch, Relics at Kelley Island, Ohio, 207

Glacial Period, Antiquity of the Last, N. S. Shaler, 529

Glacial Pleistocene Deposits, Classification of the, Prof. T. C. Chamberlin, 504; Prof. T. McK. Hughes, 504; Mr. McGee, 504

Glaciers discovered in Caucasus, New, 452

Glaciers, Snow-slips of the Kazbek, Dr. Woeikof, 600

Glaciers, the Variation of Alpine, 389

Meteorological Phenomenon, Francis Galton, F.R.S., 234;

Meteorological Observations at Sydney for January 1891, 304; Zodiacal Light as related to Aurora, O. T. Sherman, 310; the Climate of Cephalonia, Dr. Partsch, 326; Meteorologitscheskij Westnik, New Russian Meteorological Journal, 326; a Curious Case of Globular Lightning, 327; the Green Ray, C. Mostyn, 352; Secular Variations of Damage by Lightning and Hail, Dr. C. Lang, 354; Rain Gauges, Thomas Fletcher, 371; Geography of the Air, Lieutenant A. W. Greely, 388; Physical and Geological Traces of Permanent Cyclone Belts, Marsden Manson, 389; Meteorology of the Eastern Seas, Dr. Doberck, 389; Annales of the Central Meteorological Office of Paris, 389; Remarkable Weather Change at Orenburg, 389; Snowdrifts on Russian Railways, 389; Cloud Heights, Kinematic Method, Prof. Cleveland Abbe, 398; Terrible Cyclone at Martinique, 416, 575; the Production of Artificial Rain in Texas, 436, 473, 594; Rain-making Experiments, 614; the International Conference at Munich, 435; the Present Methods of reducing Meteorological Measurements, Prof. H. Mohn, 436; Prof. W. von Bezold on the Theory of Cyclones, 437; M. Lancaster on Normal Temperature in Europe, 437; H. Morize on the Climatology of Brazil, 437; Typhoon at Kobe, 437; Meteorology of Mauritius, 451; of Cape Colony, 452; Mountain, Meteorology, A. L. Rotch, 464; the Various Kinds of Gradients, L. Teisserenc de Bort, 464; Climatic History of Lake Bonneville, R. de C. Ward, 464; Maritime Meteorology Routes for Steamships between Aden and the Straits of Sunda, 476; Symons's British Rainfall, 1890, 477; Extraordinary Rainfall (1890) in Australia, Charles Todd, 501; Damage by Lightning to State Buildings in Prussia, 1877–86, 501; Remarkable Atmospheric Effect in Mediterranean during July, 502; Mountain Meteorology, A. L. Rotch, 512; the Bergen Point Tornado, W. A. Eddy, 512; Hot Winds of California, Lieutenant J. P. Finley, 512; Meteorology of Northern Afghanistan, W. L. Dallas, 529; Weather Reports of the Meteorological Council for 1880 and 1887, 529; Weather Record of the Fourteenth Century, 538; Weather Cycles, Prof. J. P. O'Reilly, 541; Weather Cycles and Severe Winters, 591; Three Atlases bearing upon the Meteorology of United States, 549; Meteorological Observations at Stations of Second Order for 1887, 549; American Weather Bureau, 598; Temperature Atlas of North America, issued by U.S. Army Signal Service, 599; Squall Oscillations in Pola and Trieste Harbours, Lieutenant Gratzl, 600; our Position with Regard to Rainfall, 630; Henri Becquerel on Underground Temperatures, 632; the International Meteorological Conference, 632; Meteorological Society, *see* Royal
Meteors: a Beautiful, Rev. J. Hoskyns-Abrahall, 162: Theory of Shooting-stars, M. Callandreau, 168; Remarkable Meteor at Ealing, 599; a Magnificent Meteor, Donald Cameron, 343; a Brilliant Meteor, August 30, 436
Metrology: Proposed International System of Weights and Measures, C. J. Hanssen, 41; Comparison of International Metre with Prototype of the Archives, M. Bosscha, 464
Metschnikoff (Dr.) and Dr. Roux, Tubercle Bacilli, 397
Meunier (Stanislas), Iron in Gold-workings about Berezowsk, 335
Mexico, American Expeditions to investigate the Flora of, 501
Mexico, M. Paul Maury's Expedition to, 598
Meyer (Prof. Ernst von), a History of Chemistry from the Earliest Times to the Present Day, Prof. T. E. Thorpe, F.R.S., 289
Meyer (Dr. Hans), an Account of the First Ascent of Kilimanjaro, 149
Meyer (Dr. Hugo), Anleitung zur Bearbeitung meteorologischer Beobachtungen für die Klimatologie, 27
Meyer (Prof. Victor), the Slow Combustion of Explosive Gas Mixtures, 354
Miall (Prof. L. C.), some Difficulties in the Life of Aquatic Insects, 457
Mica as an Invariable Dielectric, 23
Mica, Dielectric Properties of, at High Temperatures, E. Bouty, 168
Micaceous Trachyte, Artificial Production of, 392
Micro-chemical Analysis, Dr. O. Lehmann on, 76
Micro-organism, a Pink Marine, Prof. W. A. Herdman, 565
Microbes, Dr. E. L. Trouessart, 173
Microcidine, a New Antiseptic, Prof. Berlioz, 232
Microscopy: the Quarterly Journal of Microscopical Science, 21; C. Haughton Gill on Diatoms, 23; Tintullus, Free-swimming Infusorian in Royal Botanic Gardens, Mr. Grenfell, 142; *Tænia lanceolata* in Duck, J. B. Rossiter, 143; New Projection Microscope, E. M. Nelson, 143; a Negative of *Amphipleura pellucida* produced with Zeiss's New $\frac{1}{16}$ of 1·6 N.A. and Sunlight, by T. Comber, 239; Nelson's Apparatus for obtaining Monochromatic Light, 239; a New Form of Student's Microscope, T. T. Johnson, 239; International Congress of Analytical Chemists and Microscopists, 574; Microscopical Society, *see* Royal
Miculesco (C.), Determination of Mechanical Equivalent of Heat, 168
Milk and Meat of Tuberculous Animals, the Alleged Danger of Consuming, Dr. Bang, 393; Prof. Arloing, 396; Prof. M'Fadyean, 396; Prof. Hamilton, 397; Prof. Nocard, 397; Dr. Hime, 397; Dr. Barlow, 397; Prof. Perroncito, 397
Mill (Dr. H. R.), Physical Geography of Clyde Sea Area, 167
Millson (Alvan), the Yoruba Country, 209
Mimicry in Spiders, E. Heckel, 451
Mind, Retirement of Prof. Croom Robertson from the Editorship of, 548
Mineralogy: Prof. T. G. Bonney, F.R.S., and General C. A. McMahon on the Crystalline Rocks of the Lizard District, 22; an Introduction to the Study of Petrology, by Dr. Frederick H. Hatch, 25; Dr. Brauner on Lanthanum, 68; the Rejuvenescence of Crystals, Prof. John W. Judd, F.R.S., 83; a New Silver Mineral, 89; Crystals of Platinum, J. Joly, 124; Precious Opal in New South Wales, 162; Elements of Crystallography, George Huntingdon Williams, Prof. John W. Judd, F.R.S., 193; Mineralogical Society, 215, 574; the Origin of Certain Marbles, 308; New Analyses of Astrophyllite and Tscheffkinite, L. E. Eakins, 310; the Minerals in Hollow Rhyolite Spherules, J. P. Iddings and S. L. Penfield, 310; Bernardinite, Is it a Mineral or a Fungus?, J. S. Brown, 310; Gmelinite from Nova Scotia, L. V. Pirsson, 310; Analyses of Kamacite, Tænite, and Plessite from Welland Meteoric Iron, J. M. Davidson, 310; Newtonite and Rectorite, New Minerals of the Kaolinite Group, R. N. Brackett and J. F. Williams, 310; Iron in Gold-washings about Berezowsk, 336; Genesis of Iron Ores by Isomorphous and Pseudomorphous Replacement of Limestone, J. P. Kimball, 463; Allgemeine chemische Mineralogie, Dr. C. Doelter, 516; Capture of a Supposed Gem Thief at Vienna, 598
Mines and Mining Department of Chicago Exhibition, 476
Minet (Adolphe), Electrolysis of Fused Salts of Boron and Silicon, 120
Mining Engineers, Federated Institution of, 65, 500
Miquel (Dr.), Manuel Pratique d'Analyse Bactériologique des Eaux, Prof. Percy F. Frankland, F.R.S., 513
Miranzai Expedition, the, 65
Missouri Botanical Garden, 101; William Trelease, 588
Mohn (Prof.), the Present Method of Reducing Meteorological Measurements, 436
Moissan (Henri): Action of Fluorine upon Phosphorus Trifluoride, 186, 333, 622; Study of Tetra-iodide of Carbon, 264
Mole, the Australian Marsupial, *Notoryctes typhlops*, Dr. P. L. Sclater, F.R.S., 449
Molecular Process in Magnetic Induction, Prof. J. A. Ewing, F.R.S., 566
Molecular Weights at Critical Point, Determination of, P. A. Guye, 144
Monaco's (Prince of) New Yacht for the Study of the Sea, 359
Moncrieff (Sir Colin), on Egyptian Irrigation, 145, 151
Mond (Ludwig): Proposed Fellow of the Royal Society, 16; Nickel-Carbon-Oxide, 188; a Volatile Compound of Iron and Carbonic Oxide, 234; Iron-Carbonyl, 304
Monkeys, Results of Hemisection of Spinal Cord in, F. W. Mott, 189
Monsoon Rains, Forecasts of the Indian, 225
Mont Blanc, Projected Observatory on, 302, 416
Monte Somma and Vesuvius, Geological Map of, H. J. Johnston-Lavis, 271
Monuments in Egypt, the Preservation of Ancient, 281
Monuments in France, the Protection of Prehistoric, 232
Moon, Bright Streaks on, the Astronomer-Royal for Scotland, 360
Moon, Dr. Copeland on Bright Streaks in the, 454
Moor (C. G.), Disposal of Sewage, 456
Moore (Spencer), the True Nature of Callus, 216
Moorland Parish, Forty Years in a, Rev. J. C. Atkinson, 122
Moose, the Habits of the, J. G. Lockhart, 114
Morgan (Prof. C. Lloyd): Force and Determinism, 249, 319

Morgan (T. H.), Pycnogonids, 49
Morize (H.), on the Climatology of Brazil, 437
Morley Memorial College, Miss Emma Cons, 469
Morphological Nature of Principle of Fecundation, Léon Guignard, 168
Morris (D.), Botanical Expedition to the West Indies, 87, 110
Morse (E. R.), Marble Quarrying in United States, 576
Morton (G. H.), Geology of the Country around Liverpool, Prof. W. Boyd Dawkins, F.R.S., 172
Morton (Mr.), Discovery of Stalactite Caves in Tasmania, 576
Mosquitoes: the Destruction of, 591; W. Mattieu Williams, 519; Dragon-flies *v.*, 491
Mostyn (C.), the Green Ray, 352
Mott (F. W.), Results of Hemisection of Spinal Cord in Monkeys, 189
Mouchez (Admiral), Annual Report of the Paris Observatory, 70
Mountain Chant, Miss Buckland on the, 511
Mountain Climbing in Greece, Dr. Philipson, 599
Mountain Meteorology, A. L. Rotch, 464, 512
Mouse and Rat, the Development of the, Dr. Arthur Robinson, 483
Müller (Prof. F. Max): Physical Religion, 219; Address on Anthropology at the British Association, 428
Mueller (Dr.), Antagonistic Action of Strychnine and Snake Poison, 162
Mueller (Baron von), Green Eucalyptus Branches as a Disinfectant, 353
Murphy (Joseph John): High and Low-Level Meteorological Observatories, 7; Electric Transmission of Power, 590
Murray (Dr. John), the Clyde Sea-Area, 232
Muscles, Stimulating, by means of Light, M. D'Arsonval, 390
Museums: Contemplated Reorganization of the Museum of Natural History, Paris, 184, 258; Museums Association, 285; County Museums, 451; Oxford University Museum, Prof. W. H. Flower, F.R.S, 619
Music: J. W. Goundry on an Instrument for giving Enharmonic Intervals in all Keys, 19; Instruments in Just Intonation, Robt. A. Lehfeldt, 519; a New Keyed Musical Instrument for Just Intonation, Dr. William Pole, F.R.S., 446
Musical Notes from Non-Musical Sands, Cecil Carus-Wilson, 322
Musquito Coast, Vocabularies from the, Dr. D. G. Brinton, 600
Mycology, Royal Morphological Research Prize of 10,000 francs awarded by the Accademia dei Lincei of Rome to Prof. Saccardo, 257
Myers (Dr. A. T.), Catalogue of the Washington Medical Library, 563
Myles (Rev. Percy W.), Death and Obituary Notice of, 598
Mylius (Dr.), Volatile Carbonyl Compounds of Platinum, 530

Nägeli (Prof. Carl Wilhelm von): Death of, 65; Obituary Notice of, D. H. Scott, 580
National Home-Reading Union, Dr. Alex Hill, 493
Natural History: New Stations in France, 135; Natural History in Public Schools, Rev. T. A. Preston, 137; Contemplated Reorganization of the Paris Museum of Natural History, 184, 258; Mr. Ridewood's Dissections in the Entrance Hall of the Natural History Museum to illustrate Variations in Deep Plantar Tendons of the Bird's Foot, 303; Additions to Bird Department of the Natural History Museum, 451; a New Mammal from Sumatra, Prof. A. A. W. Hubrecht, 468; a Dog Story, John Bell, 521; Mr. O. F. Cook's Projected Natural History Expedition to Liberia, 548; Systematic List of the Frederick E. Edwards Collection of British Oligocene and Eocene Mollusca in the British Museum, Richard Bullen Newton, 610
Natural Science at Royal Holloway College, Appointment of Miss M. W. Robertson to Resident Lectureship in, 231
Natural Selection, Variation and, Dr. Alfred R. Wallace, 518
Nautical Almanac, 593
Naval Architects, Institution of, 305
Naval Exhibition, Royal, 180
Nelson (E. M.), a New Projection Microscope, 143
Nelson's Apparatus for obtaining Monochromatic Light, 239
Neptunia, 135
New Gallery of British Art, 255
New Guinea, British, Art and Ornament in, Prof. A. C. Haddon, 188
New Mexico, Mr. C. L. Walker's Archæological Researches in South-West, 576
New South Wales: Sydney Biological Station, 39; Precious Opal in, 162; Butter Export from, to England, 303; Dairy Work in, 436; Royal Society of, 440; Department of Agriculture in, 451
New York, Kindergarten System in, 502
New Zealand: Journal of Science, Revival of, 18; Bees in, G. M. Thomson, 19; Sparrows and Hawk in, J. W. Kirk, 529; the Basking Shark in New Zealand Waters, T. F. Cheeseman, 576
Newman (A. E. S. C.), the Chemical and Bacteriological Examination of Potable Water, 74
Newton (Prof. A., F.R.S.): the Holarctic Region, 197; *Notoryctes typhlops*, 493
Newton (Prof.), on the Action of Jupiter on Comets, 453
Newton (Richard Bullen), Systematic List of the Frederick E. Edwards Collection of British Oligocene and Eocene Mollusca in the British Museum (Natural History), 610
Newtonite, a New Mineral of the Kaolinite Group, R. N. Brackett and J. F. Williams, 310
Niagara, Falls of, Proposal to Utilize the Power wasted in the, Sir W. Siemens, 521
Nias, Island of, Ethnological Collection from, 68
Nicaragua, the Amerrique Indians of, J. Crawford, 502
Nicholson Institute, Leek, 549
Nickel, Compounds of Dextrose with the Oxides of, A. C. Chapman, 71
Nickel, Effect of Heat upon Magnetic Sensibility of, S. Bidwell, F.R.S., 187
Nickel under Influence of Hydrochloric Acid, P. Schatzenberger, 336
Nickel, Note on the Physiological Action of Carbon-Monoxide of, Dr. John G. McKendrick, F.R.S., and W. Snodgrass, 70
Nickel-Carbon-Oxide, L. Mond, F.R.S., 188
Nickel-Carbon-Oxide and Metallic Nickel obtained therefrom, 455
Nickel-Steel, Determination of Constants and Coefficients of, E. Mercadier, 264
Nicobar Pottery, E. H. Man on, 512
Nipher (Prof. F. E.), on the Fuuctions and Nature of the Ether of Space, 471
Nitrates, Reduction of, by Sunlight, 24
Nitrification, R. Warington, 190
Nitrobenzenes, Heats of Combustion and Formation of, MM. Berthelot and Matignon, 360
Nocard (Prof.), Tuberculosis, 397
Noelting (Dr.), New Method of Preparing Azoimide, 600
Nordenskiöld's (Baron), Antarctic Expedition, 231
Norfolk Geologist, the Life and Work of a, 612
North America, Forestry in, Prof. W. R. Fisher, 60
North America, the Ice Age in, G. Fredk. Wright, Prof. T. G. Bonney, F.R.S., 537
Notes on Birds and Insects, J. J. Walker, F.R.S., 565
Notoryctes typhlops, the New Australian Marsupial Mole, 135, 188; Dr. P. L. Sclater, F.R.S., 449; Prof. Alf. Newton, F.R.S., 493
Nudibranchiate Mollusca, Herdman and Chubb on, 482
Nudibranchiates, Development of Liver of, H. Fischer, 144
Numerals, Colour-Associations with, Dr. Edward S. Holden, 223
Nunivak Islanders, the, Ivan Petroff, 477
Nuovo Cimento, 136
Nuovo Giornale Botanico Italiano, 21, 236, 359

Observatories: Annual Report of the Paris Observatory, 70; Harvard College, 115; the Annual Visitation of the Royal Observatory, 129; Publication of the Vatican, 136; Physical Observatory established at Smithsonian Institution, 161; Prof. Pritchard's Report on Oxford University, 184; the Smithsonian Astro-Physical Observatory, 254; Observatory of Yale University, Dr. Elkin, 283; Proposed Astronomical, on Mont Blanc, 302, 416; the Madras, 388; an Astronomer's Work in a Modern Observatory, Dr. David Gill, F.R.S., 603
Observatories, Meteorological, High and Low Level: Joseph John Murphy, 7; Barometer at Ben Nevis in Relation to Wind, Dr. A. Buchan, 167
Ogden (William B.), Bequest to the University of Chicago, 388
Ohio, the Glacial Epoch Relics at Kelley Island, 207

Old Standards of Weights and Measures, 280
Olenellus Zone, the Discovery of, in the North-West Highlands of Scotland, Sir Archibald Geikie, F.R.S., 479
Olive-Growing in Australia, Principal Thomson, 501
Omond (R. T.), the Winds of Ben Nevis, 191
Ontario, Wolves in, 18
Opal in New South Wales, Precious, 162
Optics: Dr. Schobben's Lantern Stereoscope, 142; Apparatus to show Greater Sensitiveness of Eye to Different Colours, Captain Abney, F.R.S., and General Festing, F.R.S., 187; an Optical Illusion, Prof. S. P. Thompson, F.R.S., 187; Refraction through a Prism, Rev. John H. Kirkby, 294; Oscillations of the Retina, A. Charpentier, 311; Instrument for the Optical Comparison of Transparent Liquids, M. Sondén, 478; on Blending of Separate Chromatic Sensations perceived by each of Two Eyes, A. Chauveau, 488; Colour Sensations excited in One Eye by Coloured Light illuminating Retina of other, A. Chauveau, 536
Orange Disease in Cyprus, A. E. Shipley, 528
Oranges, Grapes, &c., the Cultivation of, in Greeee and Australia, 630
Ordnance Survey, the, 112; H. T. Crook on the, 508
Oregon, Discovery of Enormous Stalactite Cavern in, 258
O'Reilly (Prof. J. P.): the Recent Earthquakes in Italy, 293; Weather Cycles, 541
Orenburg, Remarkable Weather Change at, 389
Organ Pipes, the Energy used by, C. K. Wead, 310
Organic Chemistry, Practical Work in, Fredk. Wm. Streatfeild, 466
Orientation, Prof. J. Norman Lockyer, F.R.S., on some Points in the Early History of Astronomy, 8, 57, 107, 199
Ormerod (Miss), Resignation of, 451, 528
Ornithology: the Crowing of the Jungle Cock, S. E. Peal, 30; B. P. Cross, 151; Antipathy (?) of Birds for Colour, 31; Annual Meeting of the German Ornithological Society, 39; Birds-nesting in Western India, Lieutenant H. E. Barnes, 42; the Soaring of Birds, S. E. Peal, 56; A. C. Baines, 520; the Wild Birds Protection Act, 65; Ornithology of Lake Victoria Nyanza, Emin Pasha, 87; Vienna International Ornithological Congress, 111; the Second Ornithological Congress, 153; the Insectivorous Birds of Victoria, C. French, 162; Dr. A. Kœnig's Ornithological Observations in Madeira and Canary Islands, 163; Nests and Eggs of Catbird, Australia, A. J. North, 207; the Cuckoo, 223; the Green Sandpiper, Duke of Argyll, F.R.S., 274; Mr. Ridewood's Dissections in Entrance Hall of Natural History Museum to illustrate Variations in Deep Plantar Tendons of Bird's Foot, 303; the Destruction of Small Birds in France, 390; Additions to Bird Department of the Natural History Museum, 451; a New Species of Albatross, Sir Walter Buller, F.R.S., 502; a Remarkable Characteristic of the Wandering Albatross, Sir Walter Buller, F.R.S., 502; the Habits of the Kingfisher, J. W. Hall, 502; the Collection, &c., of Birds' Eggs and Nests, C. Bendire, 502; the Bird Collections in the Oxford University Museum, Dr. P. L. Sclater, F.R.S., 518; Water-birds that Live in the Woods, G. B. Sennett, 529; Sparrows and Hawk in New Zealand, T. W. Kirk, 529; a Wild Duck's Forethought, W. Prentis, 550
Orrery, Messrs. Philip and Sons' New, 501
Ostrich in Nesting Season, Pugnacity of Male, James Andrew, 452
Ostwald (Wilhelm), Outlines of General Chemistry, 561
Oviparous Species of Peripatus, Arthur Dendy, 468; Prof. A. Sedgwick, F.R.S., 494
Oxford: University of, Increased Accommodation for Medical and Science Schools, 111; Agricultural Education, 183; Prof. Pritchard's Report on the Observatory, 184; Oxford Summer Meeting of University Extension Students, 256; Report of Oxford University Extension Delegates, 451; the Bird Collections in the Oxford University Museum, Dr. P. L. Sclater, F.R.S., 518; Oxford University Museum, Prof. W. H. Flower, F.R.S., 619
Oxygen by Plants at Low Temperatures, Disengagement of, H. Jumelle, 216
Oyster Disease and its Remedies, Mr. Fryer, 233
Oyster Fisheries, Mr. Fryer, 233
Oyster, Mud, of New South Wales, 437
Oysters and all about them, John R. Philpots, the Oyster, a Popular Summary of a Scientific Study, Prof. W. K. Brooks, 490

FOSSIL INSECTS.

The Fossil Insects of North America, with Notes on some European Species. By Samuel H. Scudder. 2 Vols. 4to, Illustrated. (New York: Macmillan and Co., 1890.)

THE name of Mr. S. H. Scudder is familiar to students of every branch of zoology through his invaluable "Nomenclator Zoologicus." Though that work alone would be sufficient to earn the gratitude of zoologists, yet the author's claims to especial distinction really rest on the results of his investigations into the structure and distribution of fossil insects, and more particularly those of North America.

The magnificent work before us, containing considerably more than a thousand pages of letterpress, and illustrated by no less than sixty-two beautifully-executed plates, as well as by numerous figures in the text, contains, in a collective form, practically the whole of the author's contributions to the history of North American fossil insects, together with much important information relating to those of Europe. In reality, however, it treats of more than is revealed by its title, since the author includes under the head of insects not only the animals usually thus designated (which he distinguishes as Hexapods), but likewise the Myriopods and Arachnids. Since the issue of the work is limited to 100 copies (each separately numbered), it is probable that it will soon acquire an adventitious value above that which it possesses from its intrinsic merits. Apart from the author's admirable account of fossil insects (in the larger sense of the term) contributed to Prof. von Zittel's "Palæontologie," the work is the only one giving an exhaustive history of the subject, and is therefore invaluable to all interested in this branch of study. And the excellent manner in which the volumes are turned out demands a meed of praise alike to author, artists, and printers. Indeed, the only serious fault in the book is that in the first volume no explanation of the plates is given otherwise than in the text, at the close of the articles they severally illustrate.

The first of the two volumes treats exclusively of the pre-Tertiary insects, and consists of a reprint of upwards of twenty articles and essays published in various serials, dating from December 1866 to September 1890. The second volume, which is a replica of the one recently issued by the U.S. Geological Survey of the Territories, formerly under the charge of the late Dr. F. W. Hayden, contains practically the whole of what has been written concerning the Tertiary fossil insects of North America, in which field the author, with one small exception, is the sole worker.

In the first volume, as we are informed in the introduction, the whole series of essays shows the manner in which the author's views have been gradually modified in certain respects with increasing knowledge; and we think he has exercised a very wise discretion in allowing the articles to stand as they were written, and thus permitting the gradual evolution of his later views to be traced.

The earliest known true insect is *Palæoblattina* of the lower part of the Upper Silurian of France, regarded by its describer as a cockroach, although considered by our author as probably one of the Neuropteroid Palæodictyoptera (p. 286); but with this exception the insects from the Upper Devonian of the United States claim the earliest position. It is, however, only (as the author tells us elsewhere) when we reach the coal-measures that we find insect-faunas of any considerable extent, such as those of France and Illinois. The Permian, if, with the author, we refer the coal of Saarbrück to the Carboniferous, is, however, poor in insects; and the Trias, with the exception of that of parts of Colorado, almost barren. The later Secondary beds of America are likewise very barren of insect-remains, so that we have to turn to Europe to gain any definite knowledge of the fauna of that date. In the Tertiaries abundant insect-faunas occur in several river and lake-basins of both hemispheres; two of the most celebrated being the Florissant basin of Colorado, and that of Œningen on the Rhine.

The wings of the Palæozoic insects being those parts of the body which are most commonly preserved in a satisfactory condition, Mr. Scudder, at the commencement of his studies, devoted particular attention to this subject; and the first volume commences with an inquiry into the relationship of the Neuropteroid insects of the North American Carboniferous to the existing Neuroptera, as exemplified by the structure of their wings. It would be out of place here to allude to the variations in the structure of the veins of the wings presented by different groups of insects, and their derivation from a common plan of structure; and we may accordingly proceed to notice the most interesting chapter in the whole volume. This is the essay on Palæodictyoptera, commencing on p. 283. Here we have a detailed account of the reasons which induced the author to separate the whole of the Palæozoic insects from the existing orders under the name of Palæodictyoptera—a term first proposed by Goldenberg in lieu of Dohrn's preoccupied Dictyoptera, which had been suggested for an order typified by the Permian *Eugereon*. This order is defined more by the generalized characters of its various members, and the lack of those special characteristics which are the property of existing orders, than by any definite peculiarities of its own. One of its most important features is, however, that the two pairs of wings are always closely similar to one another, being equally membranous, and with the six principal veins always developed. With the exception of a few cockroach-like insects found in the American Trias, the Palæodictyoptera not only includes all the insects of the Palæozoic, but is restricted to that period, and is, therefore, extremely convenient to the geologist. The order is divided into various sections, which are severally regarded as the ancestors of the existing orders whose names they bear. Thus, the Palæozoic cockroaches constitute the Orthopteroid Palæodictyoptera; while we have a Neuropteroid section represented by *Platephemera*, *Miamia*, &c.; and an Hemipteroid one by the above-mentioned *Eugereon*. The presence in wood of Carboniferous age of borings similar to those made by modern Coleoptera, further suggests the existence of a Coleopteroid section of the order. The author (p. 320) considers that such Coleopteroids "at first showed no greater distinction between the front and hind wings than existed in other Palæodictyoptera; but afterwards those races were preserved in which the thickening of the membrane of the upper wings the better protected the insects in their burrows for the marriage flight in open air."

The author gives a still fuller account of the reasons for adopting the order Palæodictyoptera, in the essay on "Winged Insects from a Palæontological Point of View" (p. 317), from which the preceding extract is taken. Great stress is there laid on the fact that the differentiation of wing-structure characteristic of modern insects did not exist in those of Palæozoic times; all of them having a common type of neuration barely admitting of division into families. The differences in the organs of the mouth, as exemplified by the biting *Progonoblattina* (a Palæozoic cockroach) and the suctorial *Eugereon*, are considered merely as physiological adaptations of no morphological value (pp. 284, 285).

The facts and arguments detailed by the author leave, then, no doubt as to the close affinities and undifferentiated characters of all the Palæozoic insects; and also that the group Palæodictyoptera includes the ancestors of a considerable number of the existing orders of insects. Since, however, all the latter are clearly divergent branches from one or more common stocks, and are in no sense ancestral to one another, the suggestion arises whether it might not be advisable to group all the existing orders together—say, under the name of the Neodictyopterine "series"; and to rank the Palæodictyoptera as a "series" of equal value, in which the various members were not sufficiently differentiated from one another to constitute "orders." It is a very significant fact that, while the Palæozoic insects show ancestral forms of those recent orders grouped together by Packard as the Heterometabola, they include no ancestral types of the more specialized orders—Lepidoptera, Hymenoptera, and Diptera—constituting the Metabola. We have, therefore, proof that these specialized types are of later date; and it thus appears that palæontological evidence is in favour of Packard's classification.[1] Of the existing orders of insects it appears, indeed, that while the Neuroptera, Orthoptera, and Coleoptera are more or less fully represented in the Trias, it is not till the Lias that we meet with Hemiptera (Rhynchota), although *Eugereon* may be taken as sufficient evidence that a Triassic member of that order must have existed. None of the Metabola are known before the Lias, the Diptera and Hymenoptera dating from that epoch, while the Lepidoptera are unknown till the Middle Jurassic.

Though space does not permit of much further reference to the true insects of the pre-Tertiary epochs, we cannot pass over the interesting essay (p. 323) on the oldest known insect larvæ. These larvæ, which appear to be very abundant in the Trias of the Connecticut River, are known as *Mormolucoides* (*Palephemera*), and there has been much discussion as to whether they indicate Coleopteroid or Neuropteroid insects. Mr. Scudder's mode of treating this difficult question is a model of palæontological induction. After carefully reviewing all the evidence, he concludes that the fossils come nearer to the larvæ of the Neuropterous families *Perlidæ*, *Ephemeridæ*, and *Sialidæ*, and that the relationship is nearest to the latter family, which belongs to the true Neuroptera. Another exceedingly interesting article (p. 433) refers to the cockroaches of the Fairplay beds, Colorado. Several of the species from these beds belong to the Palæodictyoptera, showing the complete interdependence of two of the veins of the fore-wing characteristic of the Palæozoic types. Others, however, are true Orthopteroid cockroaches, and we thus seem to have presented to our view the very period when the Palæodictyoptera were passing into the Orthoptera. From the mingled Palæozoic and Mesozoic facies presented by their insect fauna, the author is disposed to refer the Fairplay beds to the Trias; although, as is so frequently the case, the plant-evidence does not accord with that presented by the animals.

Passing to the Palæozoic Myriopods, we notice that while all the forms described in the earlier essays are clearly referable to extinct ordinal groups, the progress of discovery has recently shown (p. 393) that side by side with these lost types there existed in the Coal-measures of Illinois Centipedes closely allied to existing forms, and belonging to the same ordinal group (Chilopoda). The essays respectively commencing on pp. 195 and 247 of the first volume give the full history of the specimens on which the author founded the orders Protosyngnatha and Archipolypoda. The former group is represented only by a single specimen from the Carboniferous of Illinois, described as *Palæocampa;* this curious creature being of small size, and in its short body, with pencils of bristles on the back, presenting a superficial resemblance to the well-known larva of the tiger-moth. Of more interest are the Archipolypoda, confined in America to the Carboniferous and Permian, although represented in the "Old Red" of Scotland. A restoration in Plate vii. A, of one of the largest of these creatures (*Acantherpestes*) gives an excellent idea of their extraordinary appearance; the animal being represented as emerging from the water and ascending the stem of a *Lepidodendron*. The figured species attained a length of about one foot; its amphibious habits being inferred from the presence of lateral apertures presumed to be branchial. The Archipolypoda agree with the Diplopoda, or Millepedes (and thereby differ from the Chilopoda), in having two ventral plates, each carrying a pair of limbs, to every dorsal plate, but differ in that each dorsal plate occupies at most only two-thirds, instead of nearly the whole of the circumference of the body. The larger species, like the figured one, were further distinguished by carrying rows of long spines on the dorsal plates. The smaller forms originally discovered by Sir J. W. Dawson in the Sigillarian stems of Nova Scotia, which were doubtless of purely terrestrial habits, and have been described as *Xylobius* and *Archiülus*, appear to indicate a distinct group of this order approximating to the modern Millepedes.

---

[1] Many authorities, attaching more importance to the nature of the metamorphosis, transfer the Coleoptera to the higher group (Holometabola), in which some also include the true Neuroptera, placing the Pseudoneuroptera with the Orthoptera.

As an instance of the danger of drawing inferences in palæontology from negative evidence, we may quote a sentence from p. 196 of the first volume, where the author states that "The Diplopoda are universally considered the lower of the two in their organization, and it is therefore not surprising to find that no Chilopoda have been found in rocks older than the Tertiary series, while Myriopods with two pairs of legs corresponding to each dorsal plate range back through the entire series of rocks to the Coal-measures." This inference is, of course, completely traversed by the above-mentioned discovery of Carboniferous Chilopoda; and it may be suggested whether the presumed coalescence of two dorsal segments in the Diplopoda and Archipolypoda is not a character in advance of the Chilopoda.

The only essay devoted to Arachnids in the first volume is the one commencing on p. 419, which was originally published for the first time in September 1890. This essay treats of the Palæozoic order Anthracomarti, and of that division of the Pedipalpi known as the Phrynidea; the Scorpions being reserved for a future occasion. The Arachnids differ from both the insects and Myriopods in being represented by an existing order (Scorpions) as far back as the Silurian. Indeed, the only extinct order of the class is the Anthracomarti, which is confined to the Carboniferous, and is regarded as having some points of connection with the Adelarthrosomata, as represented by the *Phalangidæ* ("Harvest-men"), and others with the Pedipalpi, the relationship being on the whole nearer to the latter. They are characterized by their somewhat depressed bodies, in which the abdomen is distinct from the cephalothorax, and consists of a single mass composed of from four to nine distinct joints; while the palpi are short, and do not terminate in pincers or claws. With the possible exception of the Scorpions, these appear to have been the most abundant of the Carboniferous Arachnids, and were represented by a number of genera; those described in the essay before us being arranged in two families and six genera. In the Phrynidean section of the Pedipalpi, containing the Spider-Scorpions, Mr. Scudder describes a new Carboniferous genus, *Græophonus*, besides giving further characters of a previously-described species of *Geralinura*, whose nearest living ally is *Thelyphonus*, of the tropical regions of Asia, America, and Australia.

Passing to the second volume, on the Tertiary insects, of which only a very brief notice can be given, we may touch upon a few points mentioned by the author in the introduction. One of the most noteworthy circumstances to which he refers is the extraordinary profusion in which insect remains have been preserved in some of the Tertiary lake-basins of North America, this being especially the case with the Florissant basin of Colorado, belonging to the Oligocene epoch. Not less remarkable is the fact that in "hardly a single instance has the same species been found at two distinct localities"; and this not only when the localities are separated by hundreds of miles, but even when they are comparatively near. The author considers that this peculiarity may be explained by the absence of exact synchronism between any of the insectiferous beds, and he is thus led to infer that insects will probably afford very valuable aid in determining geological horizons, the modification of species having progressed much more rapidly than is the case with plants.

Another point to which attention is directed relates to the extraordinary number of forms known only by a single specimen; the author stating that, in beds whence thousands of insects have been obtained, every third or fourth specimen will prove to be a new form. The interest of these investigations is enhanced by the discovery that a considerable proportion of the Tertiary insects must be referred to extinct genera; the author considering that a large number of the species he has placed in existing genera will eventually have to be removed to new ones. We trust, however, that Mr. Scudder will not burden the science with more new terms than are absolutely essential; more especially since, if he favours us with a new edition of his "Nomenclator," he will have the additional labour of recording them a second time.

Following the introduction there is a chapter devoted to the American localities where fossil Tertiary insects are most abundantly found. In addition to the Florissant basin of Colorado, there are deposits of approximately the same age on the White River in Colorado and Utah, as well as on the Green River in Wyoming. Less productive spots include a town in Wyoming, rejoicing in the appropriate name of "Fossil," as well as various places in British Columbia, Ontario, and Pennsylvania. There are also a certain number of insects—mostly Coleoptera—from Pleistocene or recent bone-caves and other superficial deposits.

By far the greater bulk of the enormous collection with which the author has had to deal was obtained from the Florissant basin; and it is to these alone that our few remaining observations will refer. The mass of material from these deposits is, however, so vast that in the present volume (large as it is) the author has found it possible to deal only with the Arachnids, Myriopods, and the Neuroptera, Hemiptera, and Orthoptera among the true insects. Some introductory remarks are, however, given as to the relative proportions in which the Lepidoptera, Hymenoptera, Diptera, and Coleoptera, are represented in these beds.

The total number of specimens of insects obtained from Florissant during the labours of a single summer is estimated to be more than double that obtained during thirty years at the celebrated European locality, Œningen.[1] A remarkable difference occurs between the relative number of species of the different orders of insects found at the two places. Thus, while at Œningen the Diptera are less than 7 and the Hymenoptera less than 14 per cent. of the whole; at Florissant they reach respectively 30 and 40 per cent. On the other hand, while the Œningen Coleoptera form nearly half of the whole number, at Florissant they fall to 13 per cent. The great percentage of Hymenoptera is due to the prodigious number of ants; in which respect, as also in the small proportion of beetles, the fauna agrees better with that of Radaboj, in Croatia, to which it likewise approximates more closely in age. It would take too much space to enter into the details of the proportions in which the various families of the different orders are represented in these beds; but it appears that, with the exception of the Lepidoptera, nearly every prevalent family may be demonstrated to have been in existence at that epoch. Among the beetles, about three-fifths belong to the normal series, and the remaining two-fifths to the weevils; water-beetles being unexpectedly scarce. Lepidoptera are rare, only eight species of butterflies, all referable to different and extinct genera, and about the same number of moths being at present known. It is of especial interest to note that, while seven of the eight butterflies belong to the *Nymphalidæ*, no less than two of these are referable to the sub-family *Libytheinæ*, the members of which, although found in every quarter of the globe, are fewer in number than many other groups, consisting only of ten species, referable to the single genus *Libythea*. It is, therefore, a legitimate inference that the *Libytheinæ* have been on the wane since the Oligocene or some later Tertiary epoch. Some writers, it may be mentioned, regard *Libythea* as the representative of a family rather than a sub-family.

In taking leave of the author, we congratulate him on the patience and perseverance which have carried him thus far through a task of unusual magnitude and difficulty, and hope ere long to have the pleasure of welcoming its completion. With the widely-scattered literature of palæontology ever increasing, the importance and value of monographs like the present, where the whole subject is collectively treated by a master-hand, cannot be too highly estimated.

R. Lydekker.

---

[1] Œningen is situated on the right bank of the Rhine, between Shaffhausen and Constance, and is in Baden, and not, as the author states on p. 26, in Bavaria.

STATISTICS OF POPULATION AND DISEASE.

Studies in Statistics. By George Blundell Longstaff. (London: Edward Stanford, 1891.)

"STUDIES" is a title appropriate to these somewhat detached investigations concerning at least three different classes of subject. The first few chapters, relating to vital statistics, are described by the author as "of an introductory and elementary character"; though the discussion which is contained in one of them, on the fluctuation of death-rates, varying according to the cause of death, does not appear to us so very rudimentary.

A great part of the book is occupied with the "growth of population": whether by "natural increase" or immigration. England and Wales alone add 1000 a day to the population of the world. "Over and above reserve men who fill up the gaps caused by death, a fresh regiment at full war strength daily marches to the front." To what quarters are they marching? The answer involves a consideration of intra-migration, as Mr. Longstaff terms the migration between the several divisions of the same kingdom. The inquiry brings into view the relatively slow increase of rural as compared with urban districts—a contrast not peculiar to the United Kingdom.

These and other facts, extracted from records accessible to all, are not absolutely new to the student of Statistics. Yet they excite gratitude, almost as much as if they were wholly due to the author; enhanced as they are by the wealth of his inferences and the luxury of his illustrations.

The statistics of the growth of America are less familiar to the English reader. By a careful analysis of the American census, Mr. Longstaff estimates that nearly one-third of the whole population (almost 28 per cent.) is "foreign"; considering as foreign not only those born of foreign parents (whether in America or elsewhere), but also *half* of those who, though native-born, have *one* foreign parent. This heterogeneity of population constitutes a grave social and political danger; particularly in the case of the rapidly-growing coloured population. In more than one sense, says the author, a black cloud may be said to hang over the future of the Republic.

Canada is not equally threatened by the dangers arising from a mixed population. Yet, even in Canada, the fact that the persons of French race form about a third part of the population, and increase more rapidly than any other known people, "cannot but be a source of anxiety and possible trouble in the future." The solidity of our Australian colonies is more perfectly satisfactory.

Surveying the British Empire, the writer exhibits the growth of the colonies relatively to the mother country during the last half-century. Whereas the ratio between the populations of the colonies and the United Kingdom was 7:100 in 1841, it had become 21:100 in 1881. Entertaining the idea of an Imperial Federation, our statistician thus estimates the balance of power in the imagined Federal Parliament. If every 100,000 of white population are entitled to one representative, then 61 per cent. of the Imperial Parliament would be English; the proportions for Scotland and Ireland would be 9 and 12 per cent. respectively.

But the political interest of these estimates must not detain us from what is perhaps the most severely scientific part of the work before us—namely, the investigation of the causes of disease. This medical portion of the volume may, as the author fears, "prove too technical for many readers"; and, perhaps we should add, critics. The student of such statistics must bring much knowledge in order to carry away much. The need of this requisite may be illustrated by one of Mr. Longstaff's examples. Certain of the curves which he traces show a remarkable correspondence between the outbursts of diphtheria and a group of other diseases, amongst which are croup and cynanche maligna. And yet between the two latter diseases and diphtheria the correspondence at some dates is not so close as the suggested theory desiderates. Diphtheria in 1859 rose enormously, while the other diseases did not rise simultaneously, or even fell. But, as we understand the matter, the theory is saved by the surmise that many cases previously ascribed to croup and cynanche maligna, were put down to diphtheria in 1859 and afterwards, when the stir created by letters in the newspapers had excited the attention of observers to the "new disease." This is one of those explanations of figures which an outsider would probably not even have thought of, and the importance of which he is little qualified to estimate.

The "ætiology" of the subject must be left to the expert. The general reader, if he cannot penetrate to the laws of causation, may at least admire the uniformity of results which the author's diagrams exhibit. The nature of some of his observations, and the labour and care which they required, are indicated in the following quotation:—

> "The object of my investigation was . . . [principally] to see whether any, and if so what, relations subsist between diseases believed to be distinct. . . . I accordingly traced eighty-nine curves representing the death-rates per million in England and Wales from as many 'alleged causes.' . . . By a simple application of the law of combinations, it will be found that to compare all these eighty-nine curves two and two together, would involve 3916 operations. Of these I have as yet actually made only 1425."

This comparison of curves representing the fluctuation of death-rates for different diseases forms some of the most beautiful pieces of statistics which we have ever seen. We may allude in particular to the comparison of erysipelas, scarlatina, rheumatism of the heart, and certain other diseases with each other and the variations in the rainfall (Plate xix.). The death-rates are shown to be parallel to each other, not only for different times, but also, in the case of three of the diseases, for different places in all the eleven registration counties of England and Wales. The splendid diagram which exhibits this manifold comparison (Plate xxi.) affords, as the author points out, a good illustration of the value of large numbers in statistical inquiries.

> "The curves for England and Wales exhibit smaller fluctuations than those for sections of the country, and the correspondences between them [between the rise and fall of death-rates for three specified diseases] are in nearly all cases much closer."

Among investigations of which the interest appeals to the mere statistician as distinguished from the medical expert, we may mention the calculation of the frequency with which coincidences between the deaths of both husband and wife from phthisis "might be expected to occur *as a pure matter of chance*, on the hypothesis that phthisis is *not* a communicable disease." By a beautiful application of the calculus of probabilities, the following conclusion is reached:—

> "It is plain, therefore, that, to show any substantial argument for the existence of infection, it would require a much larger collection of cases than has yet been published."

Another inquiry which the general reader will follow with peculiar interest relates to hydrophobia. The statistics suggest laws very different from popular beliefs. The paucity of the observations, however, necessitates caution; which Mr. Longstaff does not fail to inculcate. It is not his least merit that he instils what may be called the logic of statistics by occasional precept, as well as by repeated examples.

OUR BOOK SHELF.

The Best Books: A Contribution towards Systematic Bibliography. By William Swan Sonnenschein. Second Edition. (London: Swan Sonnenschein and Co., 1891.)

THE idea of this "contribution towards systematic bibliography" is excellent, and has been excellently carried out. When interest in a subject has been excited, the first question of the student, of course, is, Who are the best and most recent authorities on the matter? The question is by no means always easily answered, for as yet there are few good subject-indexes, and the most valuable of them are not within the reach of everyone. The present volume may almost be said, for ordinary practical purposes, to have solved the problem. Mr. Sonnenschein has not attempted anything so ambitious as a philosophic classification of the sciences. He has worked out his scheme on what he properly calls "a common-sense plan," grouping books first into large classes, then breaking them up into sections, sub-sections, and paragraphs—"with the result of obtaining all the literature of one subject in one list, and that of outlying subjects close at hand." He begins with theology, next takes mythology and folk-lore, then philosophy, society (including many different branches), geography, history, archæology, and so on, until all important departments of knowledge have been included. No one who has occasion to use the book will have the slightest difficulty in understanding the principle, or in finding the particular subdivision presenting the facts of which he is in search. The new edition contains the titles of twice as many books as the first edition (50,000 as against 25,000); and, so far as we have been able to examine them, they seem to have been admirably selected. Here we have to do only with the scientific part of the work; and, considering how vast is the material from which Mr. Sonnenschein had to choose his lists of scientific treatises, he may be congratulated on the manner in which his task has been accomplished. For the most part, he refers only to books that are in print, and easily obtainable. The very best books he has "asterisked," and in every case he gives the dates of the first and last editions, with the price, size, and publisher's name. Two separate indexes—one, a list of authors, with the titles of their works; the other, a list of subjects—add greatly to the value of the compilation.

The Fairyland Tales of Science. By the Rev. J. G. McPherson. Second Edition. (London: Simpkin, Marshall, and Co., 1891.)

THIS volume consists of a number of papers which appeared originally in various periodicals. The author does not profess to embody in them the results of independent research. His object is to give to readers who may not have access to recent scientific authorities "an accurate and at the same time interesting account of the remarkable discoveries in science during the last decade." This object he attains. His style is clear and straightforward, and, without being "sensational," he knows how to present facts and principles in a way that is likely to arrest attention and awaken curiosity. Among the subjects dealt with are the formation of dew, the colour of water, dust and fogs, lightning, sun-spots, after-glows, the enumeration of organisms in air, micro-organisms in water, and characteristics of deep-sea fishes. The first edition was issued about two years ago. In the present edition the author has added a few notes to bring the facts up to date.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

County Councils and Technical Education.

YOUR article of April 30 (vol. xliii. p. 602) is scarcely fair to the London County Council.

When you allege that the Council "*have 'grabbed' a fund, ear-marked for educational purposes,*" you assume the question at issue. The only way in which the fund in question is "ear-marked" for educational purposes is by a clause in the Act which gives each Council a discretionary power to apply the fund either to those purposes or to other purposes, as they choose.

London, which, as proved by Mr. Goschen, is exceptionally rated, has come badly off in the general scramble for Imperial doles which are devoted to the alleviation of rates; and if the representatives of London ratepayers treat this additional dole out of the beer and spirit duties as a make-up for their comparatively small share of other doles, they are doing not only what the law allows, but what equity justifies.

I believe, however, that amongst those who voted against the plan proposed by the Committee of the Council there are many who would not be unwilling to see the money devoted to education, if any well-considered and reasonable plan were proposed for this purpose.

But there are several questions which have to be answered before this can be done properly.

What do the promoters of "technical education" mean by that term? It is not to be the teaching of the elementary school; it is not to be the training of the workshop; but between these two extremes all is uncertain. The counties say, "instruction in the elements of farming"; the London County Council Committee says, "Polytechnics"; the statute says, "whatever the authorities at South Kensington define it to be." Educational reformers generally, so far as I can judge, mean by it all or any forms of secondary education, *i.e.* of the education which carries forward the work of the elementary school, and brings the pupil nearer to the business of life. But we need to be a good deal more precise before we establish a precedent and a practice.

Then, again, is it wise for the London County Council, which has work enough on its hands in looking after the physical condition of this great City, to take upon itself a task for which it is in no way fitted, and which was not contemplated when it was elected? Is it wise to muddle administration by first intrusting one part of education to one elective body—viz. the School Board—and then intrusting another part of it to a different elective body chosen for a different purpose?

Whilst such questions as these remain unanswered, the London Council exercises a wise discretion in not committing itself to any scheme for appropriating this fund, the offspring of a legislative fluke, to any special and permanent object.

You speak, as persons in general speak, of the London County Council as one amongst other County Councils. The name County Council is a misnomer which leads to constant errors. The London County Council has little or nothing in common with the bodies which have taken the place of the old magistracy in most districts. It is really the chief Town Council of the largest city or aggregation of cities in the world, and the rules and reasoning which, under the ill-drawn and ill-digested Local Government Act, are applied to both, are often singularly inappropriate. Calling London a county is the parent of endless mistakes; and to abuse the London Council because it is not acting in the same way as the Councils of counties seem disposed to act is no less confused than unfair. T. H. FARRER.

May 5.

The Alpine Flora.

I HAD not intended to continue the discussion on this subject, but Prof. Henslow's last letter calls for a few remarks. My argument, summed up, is as follows:—

(1) Alpine plants as a class show certain characters, *e.g.* dwarfing and compact growth.

(2) These characters are advantageous to them, or are correlated with such as are advantageous.

(3) Although dwarfing, &c., may be produced as the direct result of environment (*e.g.* poor soil), there is normal variability in respect to size, time of maturing, &c.

(4) When in cultivation those plants are selected which show a natural tendency to dwarfing, &c., it is found that the character is inherited; and in this way, dwarfed, early-maturing, and other peculiar races can be produced.

(5) On the other hand, when plants have been dwarfed from growing in poor soil, or otherwise as the result of environment acting directly upon them, there *appears* to be no evidence to show that the peculiarity is inherited.

(6) Supposing natural selection to be the only factor, it is fully competent, working on the normal variability, to produce the results observed, *so far as they are hereditary*. At least, so it seems to me.

To illustrate the point, take *Mertensia* again. In Colorado, *M. sibirica* grows in ravines, &c., by creeks; it could not possibly grow in the same way above timber-line, with its tall stems and abundant foliage. Yet it gains much advantage in the creek-bottoms from its height and rank growth; if it were a dwarf, it would be almost or altogether smothered. Above timber-line, on the Sangre de Cristo Range, I found the dwarf species, *M. lanceolata*. Thus we have two species frequenting different situations in the same district: each is fitted for its station; either, removed to the station of the other, could not exist. In Arctic regions, *M. sibirica* has produced a dwarf variety called *drummondii*, which is, I suppose, a first step towards the establishment of a dwarf Arctic species.

Prof. Henslow asks why, if natural selection eliminates tall plants on Alpine summits, it does not also do so lower down? I am not at all clear that it does not, in some cases. For example, why is it that plants growing on exposed sea-shores have a tendency to lie upon the ground or otherwise to evade the violence of the winds? But when a plant is growing among others, it has to compete with them in raising itself into conspicuousness, and any slight disadvantage from exposure to the winds would be more than compensated by the advantage of being able to spread its flowers and foliage in the sunlight and attract insects.

The only plant of any size I found above timber-line on the Sangre de Cristo Range was *Cnicus eriocephalus*, a wonderful great thistle, with bright chrome-yellow flowers, which are visited by humble-bees. But this plant is very prickly and woolly, and its heads are nodding; it is, though it seems paradoxical to say so, a gigantic dwarf.

The splendid *Primula parryi* shows its crimson flowers by creeks at very high altitudes in Colorado; an allied but *very small* species lives above timber-line in the same districts, called *P. angustifolia*. These are true species; *angustifolia* is not starved or frozen *parryi*. Now *P. parryi* is coming into cultivation, it would be interesting to see whether it could be modified by environment in the direction of *angustifolia*, and how far such modification would be inherited.

There are other matters one might discuss, but I think I have already written enough. I merely ask, will Prof. Henslow give a case in which the direct effect of environment *has* produced inherited dwarfing? Will he also show that natural selection cannot produce a dwarfed variety, or that artificial selection has not? T. D. A. COCKERELL.

3 Fairfax Road, Bedford Park, Chiswick, W., April 27.

MR. THISELTON-DYER, in his interesting letter in NATURE (p. 581), does not mention one of the striking characteristics of the Alpine flora—the remarkable brilliancy of the flowers, as compared with those borne by the same or similar species in

England. A comparison of this kind made by the memory is no doubt not severely scientific, but those tourists in Switzerland who are in the habit of observing flowers will probably confirm the statement. Plants grown at high levels in the Alps are, as Mr. Dyer says, above a great screen of aqueous vapour, and I have in my own mind always put down the greater brilliance of Alpine flowers to their getting more sun than in our cloudier climate. It is not, however, solely any alteration in the actual effects of the solar rays, caused by this absence of aqueous vapour, that makes the colours of Swiss flowers so bright. The same, or, I should assert from memory, even greater, brilliancy, will be found in Arctic and sub-Arctic Norway by anyone who visits the Throndhjem district and the coast to Hammerfest in June. Western Norway notoriously is one of the moistest parts of Europe; but, on the other hand, it has, broadly speaking, no night at midsummer. It is thus apparently the quantity, and not the quality, of the sunlight that causes the peculiarly vivid colours of Swiss flowers, including those of the pastures from 2000 feet upwards. I have never been in Switzerland in spring, and I cannot therefore judge whether the colours of the flora in the lower districts are also more brilliant than ours; but it will be seen below that Swiss observers find that the high Alpine flora is much more brilliant than the same plants in the lowlands.

Our great national garden at Kew is peculiarly badly situated for the growth of Alpines. The situation is low and foggy, and mild muggy weather alternates with night frosts. Above all, the smoke pall of London is peculiarly destructive in connection with the other disadvantages of the site. Alpine plants, as Mr. Dyer shows, are, in their natural state, at rest under a cloak of snow during the winter. The least warmth, however, starts them into growth, and the marvellously rapid flowering of many kinds in the ooze on the melting of a snow-bed, is one of the most curious sights of the Alps. The Kew climate (and the general English one too, though to a lesser degree) keeps the plants in growth in winter. Then fogs, smoke, and damp collect on the young growth. These enemies are peculiarly liable to attach themselves to the numerous sorts with hairy or woolly leaves. Then follow night frosts, and the young growth perishes.

The application of these remarks is, that it does not follow that, because cold frames are necessities in the culture of Alpines at Kew, they should be used elsewhere in England. There has been a long discussion recently on this very point in the gardening papers, and the general belief appears to be, that given a fairly dry climate cold frames are *injurious*, because they excite and keep plants in growth when they should be at rest. A sheet of glass suspended over a plant in the open air, so as to shoot off our superfluous rain and to keep off some of our fog, appears to be much better, for premature growth is not stimulated. Alpines should so far as practicable be kept as dry as we can in winter, by drainage, light soil, &c. Then when growth commences, say in March, they should be well watered each day (unless it is raining), early in the morning. The plentiful moisture thus supplied to some degree takes the place of the melting snow, and it has dried off before the evening frosts seize upon the leaves. The plants thus can grow freely in the day because they are surrounded with a moist atmosphere, and they are kept "stocky" (in gardeners' phrase) by the cold at night, just as they are in fact on the Alps. This is the plan recommended by that great authority M. H. Correvon, of the Jardin Alpin d'Acclimatation, Geneva. In the drier climate of that city, M. Correvon replaces the snow blanket of the Alps by pine boughs fastened closely over his Alpines. In England this would, I fear, only make the plants rot. It does not follow that, because many plants in frames at Kew grow long and straggling and lose their natural habit, they do so in England generally in the open air. The changes in the habits of Alpines are largely due to changes in soil. For instance, the Edelweiss (*Gnaphalium leontopodium*) grows perfectly freely from seed anywhere about London, but the flowers lose their compactness. I am told, however, that if plenty of lime is added to the soil they become as compact and close as in Switzerland.

In "Les Plantes des Alpes" (Geneva, Jules-Carey) M. Correvon very fully explains his views, formed, after great practical experience, on the conditions of the Alpine flora. Your space will not allow me to make many quotations from a work of the utmost interest both theoretical and practical, but the following bears on my point as to the brilliant colours of Alpine flowers:—

"Ces végétaux sont 'reine Kinder des Lichtes,' comme les a appelés un poète allemand; on ne trouve pas de champignons dans les Alpes, ni aucune plante qui n'appartienne franchement au domaine de la lumière. Aussi les espèces de nos plaines qui se trouvent transportés là-haut sont-elles parées de couleur bien plus vives, bien plus pures qu'elles ne sont chez nous."

M. Correvon gives a number of instances in support of this, which I will not quote here. In conclusion, is Mr. Dyer correct in thinking that the soil in the high Alps is permanently frozen with the exception of a slight film on the top? I am aware that when you get to considerable elevations the subsoil is frozen. For instance, I was told that the reason for the well-known mortuary on the Great St. Bernard was that bodies could not be buried there. But a great many of the flowers generally called Alpines grow below the tree limit of 6000 or 6500 feet, and few are to be found above 8000 feet. If the subsoil on the higher Alps is frozen, it would not apparently be so where trees grow, and it would be interesting to know the line of subterranean frost, and at what depths below the surface it is permanent at various elevations. J. Innes Rogers.

Chislehurst, April 27.

Co-adaptation.

I do not propose to extend the discussion on this subject beyond the present communication, but I cannot refrain from calling attention to the remarkable discrepancy in the position taken by Dr. Romanes in his last letter (April 23, p. 582), and that in his former communication (March 26, p. 489), in which he says:—"I do not . . . hold myself responsible for enunciating Mr. Herbert Spencer's argument, which the quotation sets forth. I merely reproduced it from him as an argument which appeared to me valid on the side of 'use inheritance.' For not only did Darwin himself invoke the aid of such inheritance in regard to this identical case . . . &c." If words have any meaning, this implies that Dr. Romanes agrees with Darwin in regarding this case as one in which "use inheritance" played a part. Now, after I have endeavoured to show that this supposed case of co-adaptation can be explained without the aid of "use inheritance" at all, Dr. Romanes says that there is no difference of opinion on this point between us. I can only say that I am very glad to learn this admission on his part, but why did he quote the argument from Herbert Spencer as "valid on the side of 'use inheritance,'" if he did not believe it to be a case of true co-adaptation? R. Meldola.

High and Low Level Meteorological Observatories.

I have read with much interest your article of the 11th inst. on the results obtained by simultaneous observations in the meteorological observatories at the base and at the summit of Ben Nevis. Ben Nevis rises to a height of only 4370 feet above the sea, and yet we find that the comparison of these observations gives results of a kind that could not be obtained from any number of stations all on the same level. Might we not hope for still more valuable results from similar observatories placed at the base and the summit of Etna and Teneriffe? Etna is 10,870 feet high, and Teneriffe 12,200. These would be better than any Alpine stations, because of their perfect isolation.

Belfast, April 25. Joseph John Murphy.

An "International Society."

An institution with the grandiloquent title of "The International Society of Literature, Science, and Art," which appears now to be largely touting for subscriptions, publishes in its prospectus a list of the "Honorary Council," among whom appears "Professor Flower." As I am the only person in this country to whom such a description could be applicable, and as many of my friends have inquired of me whether I have really given my support to the institution, I wrote to the secretary to inquire by what authority the name appeared, and received the following reply, which needs no comment:—

"Sir,—We beg to acknowledge the receipt of your favour of Saturday. The gentleman to whom you refer is the well-known Professor Ogilby Flower, of New York. I am sorry the coincidence should have caused you any annoyance. In future printings of our prospectus the Christian name shall be inserted, so that no misunderstanding may exist."

Although this letter was dated March 9 last, I find that the prospectus continues to be issued unchanged, otherwise I should not have cared to trouble you with what may appear a small personal matter. I may mention that there are other names upon the list which present as great or even greater difficulties of identification. W. H. Flower.

British Museum (Natural History), May 2, 1891.

ON SOME POINTS IN THE EARLY HISTORY OF ASTRONOMY.[1]

II.

WE have next to deal with the astronomical relations of the horizon of any place, in connection with the worship of the sun and stars at the times of rising or setting, when of course they are on or near the horizon; and in order to bring this matter nearer to the ancient monuments, we will study this question for Thebes, where they exist in greatest number and have been most accurately described.

The French and Prussian Governments have vied with each other in the honourable rivalry of mapping and describing the monuments. The French went to Egypt at the end of the last century, while the Scientific Commission which accompanied the army, a Commission appointed by the Institute of France, published a series of volumes containing plans of all the chief temples in the valley of the Nile, as far as Philæ.

In the year 1844, after Champollion had led the way in deciphering the hieroglyphics, we became almost equally indebted to the Prussian Government, who also sent out a Commission to Egypt, under Lepsius, which equalled the French one in the importance of the results of the exploration; in the care with which the observations were made, and in the perfection with which they were recorded. Hence it is that in attempting to get information from ancient temples it is wise to study the region round Thebes, where the information is so abundant and is ready to our hand.

We have then to consider an observer on the Nile at Thebes, and to adjust things properly we must rectify the globe to the latitude of 25° 40′, or, in other words, incline the axis of the globe at that angle to the wooden horizon.

It will be at once seen that the inclination of the axis to the horizon is very much less than in the case of London. Since all the stars which pass between the North Pole and the horizon cannot set, all their apparent movement will take place above the horizon. All the stars between the horizon and the South Pole will never rise. Hence, stars within the distance of 25° from the North Pole will never set at Thebes, and those stars within 25° of the South Pole will never be visible there. At any place the latitude and the elevation of the pole are the same. It so happens that all these places with which archæologists have to do in studying the history of early peoples, Chaldæa, Egypt, Babylonia, China, Greece, &c., are all in middle latitudes, therefore we have to deal with bodies in the skies which do set and bodies which do not, and the elevation of the pole is neither very great nor very small. In each different latitude the inclination of the equator to the horizon as well as the elevation of the pole will vary, but there will be a strict relationship between the inclination of the equator at each point and the elevation of the pole. Except at the poles themselves the equator will cut the horizon due east and due west. Therefore everything to the north of the equator which rises or sets will cut the horizon between the east or west point and the north point; those bodies which do not set will of course not cut the horizon at all.

The sun and stars near the equator, in such a latitude as that of Thebes, will appear to rise or set at no very considerable angle from the vertical; but when we deal with stars rising or setting near to the north or south points of the horizon they will seem to skim along the horizon instead of rising directly.

Now it will at once be obvious that there must be a strict law connecting the position of the sun or a star with its place of rising or setting. Stars at the same distance from the celestial pole or equator will rise or set at the same point of the horizon, and if a star does not change its place in the heavens it will always rise or set in the same place. Here it will be convenient to introduce one or two technical terms: we generally define a star's place by giving, as one ordinate, its distance in degrees from the equator: this distance is called its declination. Further, we generally define points on the horizon by dividing its whole circumference into 360°, so that we can have *azimuths* of 90° from each pole to the east and west points. We also have *amplitudes* from the east and west points towards each pole. We can say then that a star of a certain declination will rise or set at such an azimuth; or at such an amplitude. This will apply to both north and south declinations.

The following table gives the amplitudes of rising or setting (north or south) of celestial bodies having declinations from 0° to 64°; bodies with higher declinations than 64° never set at Thebes if they are north, or never rise if they are south, as the latitude (and therefore the elevation of the pole) there is nearly 26°.

Amplitudes at Thebes.

This being premised, we now pass to the yearly path of the sun, with a view of studying the relation of the various points of the horizon occupied by the sun at different times in the year. In the very early observations that were made in Egypt, Chaldæa, and elsewhere, when the sun was considered to be a god who every morning got into his boat and floated across space, there was no particular reason for considering the amplitude at which the boat left, or came to, shore. But a few centuries showed that this rising or setting of the sun in widely varying amplitudes at different parts of the year depended upon a very definite law. We now, of course, more fortunate than the early Egyptians, know exactly what this law is. We saw in the last lecture that not many years ago Foucault gave us a means of demonstrating the fact that the earth rotates on its axis. We have also a perfect method of demonstrating that the earth not only rotates on its axis once a day, but that it moves round the sun once a year, an idea which was undreamt of by the ancients. As a pendulum shows us the rotation, so the determination of the aberration of light demonstrates for us the revolution of the earth round the sun.

---

[1] From shorthand notes of a course of lectures to working men delivered at the Museum of Practical Geology, Jermyn Street, in November 1890. The notes were revised by me at Aswan during the month of January. I have found, since my return from Egypt in March, that part of the subject-matter of the lectures has been previously discussed by Herr Nissen, who has employed the same materials as myself. To him, therefore, so far as I at present know, belongs the credit of having first made the suggestion that ancient temples were oriented on an astronomical basis. His article is to be found in the *Rheinisches Museum für Philologie*, 1885. Continued from vol. xliii. p. 563.

We have, then, the earth endowed with these two movements—a rotation on its axis in a day, and a revolution round the sun in a year. To see the full bearing of this on our present inquiry, we must for a time return to the globe or model of the earth.

To determine the position of any place on the earth's surface we say that it is so many degrees distant from the equator, and also so many degrees distant from the longitude of Greenwich: we have two rectangular coordinates, latitude and longitude. When we conceive the earth's equator extended to the heavens, we have a means of determining the positions of stars in the heavens exactly similar to the means we have of determining the position of any place on the earth. We have already defined distance from the equator as north or south declination in the case of a star, as we have north latitude or south latitude in case of a place on the earth. With regard to the other co-ordinate, we can also say it is at a certain distance from our first point of measurement, whatever that may be, along the celestial equator; speaking of the stars we call this distance right ascension, as speaking of matters earthy we measure from the meridian of Greenwich and call this distance longitude.

The movement of the earth round the sun is in a plane which is called the plane of the ecliptic, and the axis of rotation of the earth is inclined to that plane at an angle of something like $23\frac{1}{2}^{\circ}$. We can if we choose use the plane of the ecliptic to define the positions of the stars as we use the plane of the earth's equator. In that case we talk of distance above the ecliptic as celestial latitude, and along the ecliptic as celestial longitude. The equator, then, cuts the ecliptic at two points: one of these is chosen for the start-point of measurement along either the equator or the ecliptic. It is called the first point of Aries.

We have, then, two systems of co-ordinates, by each of which we can define the position of a star in the heavens: equatorial co-ordinates dealing with the earth's equator, ecliptic co-ordinates dealing with the earth's orbit. Knowing that the earth moves round the sun once a year, the year to us moderns is defined with the most absolute accuracy. In fact, we have three years: we have a sidereal year—that is, the time taken by the earth to go through exactly 360° of longitude; we have what is called the tropical year, which indicates the time taken by the earth to go through not quite 360°, to go from the first point of Aries till she meets it again; and since the equinoctial point advances to meet the earth, we talk about the precession of the equinoxes; this year is the sidereal year minus twenty minutes; then there is also another year called the anomalistic year, which depends upon the movement of the point in the earth's orbit where the earth is nearest to the sun; this is running away, so to speak, from the first point of Aries, instead of advancing to meet it, so that in this case we get the sidereal year plus nearly five minutes.

The angle of the inclination of the earth's plane of rotation to the plane of its revolution round the sun, which, as I have said, is something like $23\frac{1}{2}^{\circ}$, is called *the obliquity of the ecliptic*. This obliquity is subject to a slight change; 6000 years ago it was over 24°.

In order to give a concrete idea of the most important points in the yearly path of the sun round the earth, I have here four globes representing the earth, with another globe in the middle representing the sun, showing the four practically opposite points of the earth's orbit, in which the north pole of the axis is most inclined to the sun; the north pole of the axis is most inclined away from the sun; and the two opposite and intermediate points where the axis is not inclined to or from the sun, but is at right angles to the line joining the earth in these two positions.

A diagram (Fig. 6) shows what will happen under these conditions. If we take the two points at which the axis, instead of being inclined towards the sun, is inclined at right angles to it, it is perfectly obvious that we shall get a condition of things in which the movement of the earth on its axis will cause the dark side of the earth and also the light side represented by the side nearest to the sun both being of equal areas, to extend from pole to pole; so that any place on the earth rotating under those conditions will be brought for half a period of rotation into the sunlight, and be carried for half a period of the rotation out of the sunlight; the day, therefore, will be of the same length as the night, and the days and nights will therefore be equal all over the world.

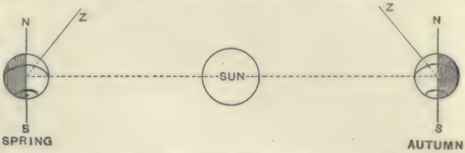

FIG. 6.—Diagram showing the equality of the sun's zenith distance at the two equinoxes. N, north pole of the earth; S, south pole; Z, zenith of Greenwich.

We call that the period of the equinoxes; the nights are of the same length as the day in both these positions of the earth with regard to the sun.

But in Fig. 7 we have a very different condition. Here the north pole is inclined at the greatest angle of $23\frac{1}{2}^{\circ}$ towards, and away from, the sun. If I take a point very near the north pole, that point will not, in summer, be carried by the earth's rotation out of the light, and a part equally near the south pole will not be able to get into it. These are the conditions at and near two other points called the solstices.

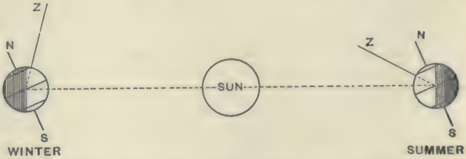

FIG. 7.—Diagram showing the variation of the sun's zenith distance from solstice to solstice. N, north pole of the earth; S, south pole; Z, zenith of Greenwich.

In each of these globes I have placed a wire to represent the overhead direction from Jermyn Street, London, and if I observe the angle between this direction of the zenith to the sun in winter I get a considerable one; but if I take the opposite six-monthly condition and take the same zenith point, I get a very small angle. In other words, under the first condition the sun will be far from the zenith of Jermyn Street, we shall have winter; and in the other condition the sun will be as near as it can be to the zenith of Jermyn Street, we shall have summer. These two points represent the two points in the earth's orbit at which the sun has the highest declination north or south. With the greatest north declination the sun will come up high, appear stationary for a day or two, as it does at our summer solstice, and then go down again; at the other point, when it has the greatest southern declination, it will go down to the lowest point, as it does in our winter, stop, and come up again—that is, the sun will stand still, and the Latin word solstice exactly expresses that idea. We have then two points in the annual revolution of the earth round the sun at which we have equal altitudes of the sun at noon, two others when the altitude is greatest and least. We get the equal altitudes at the equinoxes and the greatest and the least at the solstices. These altitudes depend upon the change of the sun's declination. The change of declination will affect the azimuth and amplitude of the sun's rising and setting, this is why the sun sets most to the north in summer and most to the south in winter. At the equinoxes the sun has always 0° Decl., so it rises and sets due east and west all over the world. But at the solstices it has its greatest declination of 23½° N. or S.; it will rise and set therefore far from the east and west points; how far, will depend upon the latitude of the place we consider. The following are approximate values:

Latitude of place. °	Amplitude of sun at solstice. °	′
25	26	5
30	27	24
35	29	8
40	31	21
45	34	40
50	38	20
55	44	0

At Thebes, representing Egypt, we find that the sun's azimuth at the summer solstice will be 26° N. of E. at rising, and it will be 26° N. of W. at setting.

These solstices and their accompaniments are among the striking things in the natural world. In the winter solstice we have the depth of winter, in the summer solstice we have the height of summer, while at the equinoxes we have but transitional changes; in other words, while the solstices point out for us the conditions of greatest heat and greatest cold, the equinoxes point out for us those two times of the year at which the temperature conditions are very nearly equal, although of course in the one case we are saying good-bye to summer and in the other to winter. To people who live in tropical or sub-tropical countries a summer solstice is a very much more definite thing than it is to us. In Egypt the summer solstice was paramount, for it heralded the rise of the Nile. Next came the autumnal equinox, for it marked the height of the inundation.

Did the ancients know anything about these solstices and these equinoxes? That is one of the questions which we have to discuss. Dealing with the monumental evidence in Egypt alone, the answer is absolutely overwhelming. The evidence I propose to bring before you consists of that afforded by some of the very oldest temples that we know of in Egypt. Among the most ancient and sacred fanes in Egypt was one at Abydos, which, the tradition runs, was built by the Shosou-Hor or servants of Horus (therefore sun-worshippers) before the time of Menes; Menes, as we have seen, having reigned at a date certainly not less than 4000, and possibly 5000 years B.C.

First a word as to the general plan of a temple such as we find it in Egypt. They may be arranged architecturally into two main groups. Edfou is the most perfect example of one of the first group, characterized by having a pylon consisting of two massive structures right and left of the entrance, which are somewhat like the two towers that one sometimes sees on the west front of some of our English cathedrals. The Temple of Ramses II. in the Memnonia at Thebes is another example (Fig. 8).

From the entrance-pylon the temple goes stretching along through various halls of different sizes and details until at last at the extreme end of the temple what is called the Sanctuary, Naos, or Holy of Holies, is reached. The end of the temple at which the pylons are situated is open, the other is closed. These lofty towers, and indeed the walls, are sometimes covered with the most wonderful drawings and hieroglyphic figures and records. Stretching in front of the pylons, extending sometimes very far in front, are rows of sphinxes. This principle is carried to such an extent that in some cases separate isolated gates have been built right in front and exactly in the alignment of the temple. At Karnak there really are two such temples back to back, and the distance which separates the outside entrances of both is greater than the distance from Pall Mall to Piccadilly; the great temple covers about twice the area covered by

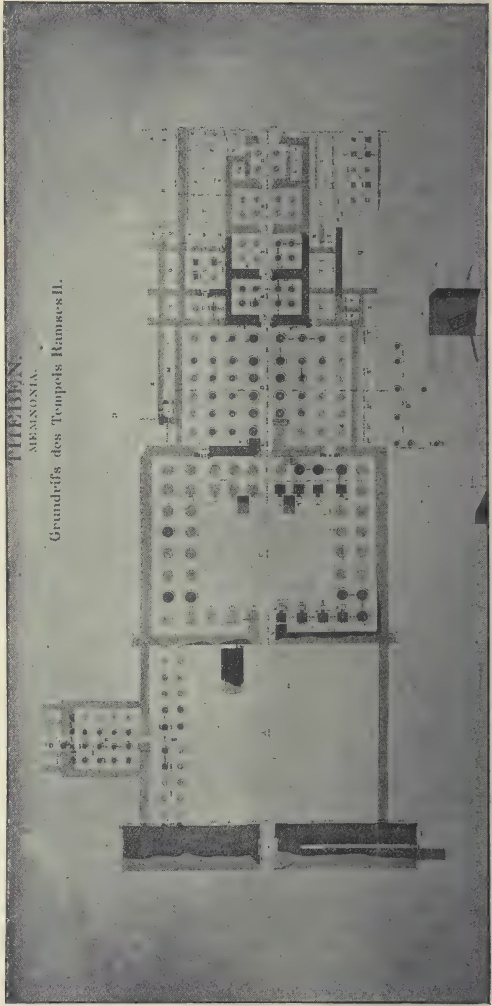

FIG. 8.—Plan of the Temple of Ramses II. in the Memnonia at Thebes (from Lepsius), showing the pylon at the open end, and the sanctuary at the closed one.

St. Peter's at Rome, so that these were temples of a vastness absolutely unapproached in the modern world.

In Denderah we have an example of the second group, in which the massive pylon is omitted. In these the front is entirely changed; instead of the pylon we have now an open front to the temple with columns—the Greek form of temple is approached (Fig. 9).

I shall not have time to get to the astronomical side of the Greek temples in this course of lectures, but I am anxious to take this opportunity to refer to the transition from the Egyptian form of temple to the Greek one. The east front of the Parthenon at Athens very much more resembles the temple of Denderah than it does the early Egyptian temple—that is to say, the eastern front is open; it is not closed by pylons.

In many Egyptian temples, in the progress from one end to the other, one goes through various halls of different styles of architecture and different stages of magnificence. But in the Greek temple this is entirely changed; the approach to the temple was outside, the temple representing, so to speak, the core, almost the Holy of Holies, of the Egyptian temple, and any magnificent approach to it which could be given, was given from the outside. But although they were quite different in their aspects, they were quite similar in their objects. Some Egyptian temples took hundreds of years to build; the obelisks were all in single blocks like that on the Embankment, and all were brought for hundreds of miles down the Nile. A temple meant to the Egyptians a very serious thing indeed.

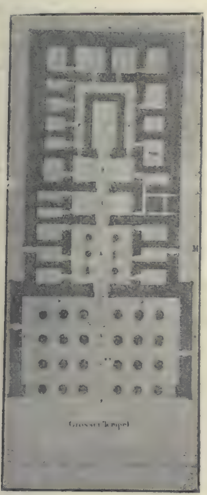

FIG. 9.—Plan of the Temple of Denderah (from Lepsius), showing the absence of a pylon.

So much, then, for a general idea of an ancient temple.

Another point is very striking in these temples, notably in the chief one at Karnak.

From one end of the temple to the other we find the axis marked out by narrow apertures in the various pylons, and many walls with doors crossing the axis. There are 17 or 18 of these limiting apertures, and in the other temple which is back to back to this one we have pylons in exactly the same way limiting the light which falls into the Holy of Holies or the Sanctuary. This construction gives one a very definite impression that every part of the temple was built to subserve a special object, viz. to limit the sunlight which fell on its front into a narrow beam, and to carry it to the other extremity of the temple—into the sanctuary—which extremity was always blocked. There is no case in which the beam of light can pass absolutely through the temple.

The idea is strengthened by considering the construction of the astronomical telescope. Although the Egyptians knew nothing about telescopes, it would seem that they had the same problem before them which we solve by a special arrangement in the modern telescope—they wanted to keep the light pure, and to lead it into their sanctuary, as we lead it to the eyepiece. To keep the light that passes into the eyepiece of a modern telescope pure, we have between the object-glass and the eyepiece a series of what are called diaphragms; that is a series of rings right along the tube, the inner diameters of the rings being greatest close to the object-glass, and smallest close to the eyepiece; these diaphragms must so be made, that all the light from the object-glass shall fall upon the eyepiece, without loss, or reflection by the tube.

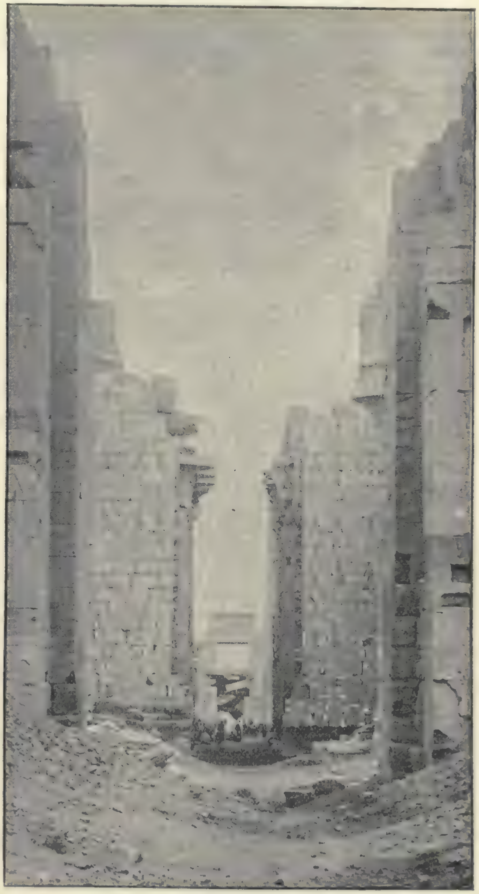

FIG. 10.—The axis of the Temple of Karnak, looking south-east, from outside the north-west pylon (from a photograph by the author).

These apertures in the pylons and separating walls of Egyptian temples exactly represent the diaphragms in the modern telescope. J. NORMAN LOCKYER.

(*To be continued.*)

HERTZ'S EXPERIMENTS.[1]

II.

IN the last article, a general method of measuring the velocity at which a disturbance is propagated was described. It depended on being able to produce a regular succession of disturbances at equal intervals of time. These were made to measure their own velocity by reflecting them at an obstacle. Then, by the interference of the incident and reflected waves, a succession of loops and nodes are produced at intervals of half the distance a disturbance is propagated during the time between two disturbances. It is a general method applicable to any sort of disturbance that takes time to get from one place to another. It has been applied over and over again to measure the rate at which various kinds of disturbance are propagated in solids, liquids, and gases. It was applied in a modified form years ago, to measure the length of a wave of light; and, within the last year, some of the most beautiful experiments on photography ever described are applications of this principle by Herr Wiener and M. Lippmann.

There are three things essential to this experiment: (1) some method of originating waves; (2) some method of reflecting them; (3) some method of telling where there are loops and where there are nodes. We will take them in this order:—

(1) How can we expect to originate electric waves? If, when a body is electrified positively, the electric force due to it exists simultaneously everywhere, of course we cannot expect to produce anything like a wave of electric force travelling out from the body; but if, when a body is suddenly electrified, the electric force takes time to reach a place, we must suppose that it is propagated in some way as a wave of electric force from the body to the distant place. This, of course, assumes that there is a medium which is in some peculiar state when electric force exists in it, and that it is this peculiar state of the medium, which we call electric force, existing in it, that is propagated from one place to another. It must be carefully borne in mind what sort of a thing this is that we call the electric force at any place. It is not a good name—electric intensity would be a better one; but electric force has come so much into use, it is hardly to be expected that it can be eradicated now. Electric force at any place is measured by the mechanical force that would be exerted at the place if a unit quantity of electricity were there. It is not a force itself at all; it is only a description of the condition of the medium at the place which makes electricity there tend to move. The air near the earth is in such a condition that everything immersed in it tends to move away from the earth with a force of about 1·26 dynes for each cubic centimetre of the body, *i.e.* each cubic centimetre tends to move with a force of 1·26 dynes. Now the condition of the air that causes this is never described as volume force existing at the place, though we do describe the corresponding condition of the ether as electric force existing there; and as volume force existing would be a very objectionable description of the condition of the air when, being at different pressures at various levels, it tends to make bodies move with a force proportional to their volume, so electric force existing is a very objectionable description of the condition of the ether, whatever it is, that tends to make bodies move with a force in proportion to their electric charges. We know more about the structure of the air than we do about the ether. We know that the structure of the air that causes it to act in this way is that there are more molecules jumping about in each cubic centimetre near the earth than there are at a distance, and we do not know yet what the structure of the ether is that causes it to act in this remarkable way; but even though we do not know the nature of the structure, we know some of its effects, by means of which we can measure it, and we can give it a name. Although we know very little indeed about the structure of a piece of stressed india-rubber, yet we can measure the amount of its stress at any place, and can call the india-rubber in this peculiar condition "stressed india-rubber." As a matter of fact, we know a great deal more about the peculiar condition of the ether that we describe as "electric force" existing than we do about the "stressed india-rubber"; and there is every reason to suppose that the structure of the ether is, out of all comparison, more simple than that of india-rubber.

When sound-waves travel through the air, they consist of compressions followed by rarefactions, and between them the pressure varies from point to point, so that here we have travelling forward a structure the same as that of the air near the earth, and waves of sound might be described as consisting of a succession of positive and negative "volume forces" travelling forward in the air: this form of expression would no doubt be objectionable, but still if all we knew about the properties of the air near the earth was that it tended to make bodies move away from the earth with a force proportional to their volume, it is quite likely that this condition of affairs near the earth might have been described as the existence of a "volume force" near the earth, and when it was discovered that this action was due to a medium, the air, it would have been quite natural to describe this state of the air as "volume force" existing in it: and then when waves of sound were observed it would be quite natural that they should be described as waves of "volume force," especially if the only way in which we could detect the presence of these waves was by observing the force exerted on bodies immersed in it, which was proportional to their volumes, and which we happen to know is really due to differences of pressure at neighbouring points in the air. We do not know what is the structure of the ether that causes it to exert force on electrified bodies, but we know of the existence of this property, and when it is in this state we say that "electric force" exists in it, and we have certain ways by which we can detect the existence of "electric force," one of which is the production of an electric current in a conductor, and the consequent electrification of the conductor, and if this is strong enough we can produce an electric spark between it and a neighbouring conductor. When a conductor is suddenly electrified, the structure of the ether which is described as electric force existing in it travels from its neighbourhood through the surrounding ether, and this is described as a wave of electric force travelling through the surrounding ether. It is desirable to be quite clear as to what is meant by the term a wave of electric force, and what we know about it. We know that it is a region of ether where its structure is the same as in the neighbourhood of electrified and some other bodies, and owing to which force is exerted on electrified bodies, and electric currents are produced in conductors.

We may, then, reasonably expect that, if it is possible to electrify a body alternately positively and negatively in rapid succession, there will be produced all round it waves of electric force—that is, if the electric force is propagated by, and is due to, a medium surrounding the electrified body, if electrification is a special state of the medium that fills the space between bodies.

(2) The next question is: How can we reflect these waves? In order to reflect a wave, we must interpose in its way some body that stops it. What sort of bodies stop electric force? Conductors are known to act as complete screens of electric force, so that a large conducting sheet would naturally be suggested as the best way to reflect waves of electric force. Reflection always occurs when there is a change in the nature of the medium, even though the change is not so great as to

---

[1] Continued from vol. xliii. p. 538.

stop the wave, and it has long been known that, besides the action of conductors as screens of electric force, different non-conductors act differently in reference to electric force by differing in specific inductive capacity. Hence we might expect non-conductors to reflect these waves, although the reflection would probably not be so intense from them as from conductors. Hence this question of how to reflect the waves is pretty easily solved. We are acting still on the supposition that there are waves at all. If electric force exist everywhere simultaneously, of course there will be no waves to reflect, and, consequently, no loops and nodes produced by the interference of the incident and reflected waves.

(3) The third problem is: How can we expect to detect where there are loops and where there are nodes? Recall the effects of electric force. It tends to move electrified bodies. If, then, an electrified body were placed in a loop, it would tend to vibrate up and down. This method may possibly be employed at some future time, and it may be part of the cause of photographic actions, for these have recently been conclusively proved to be due to electric force; but the alternations of electric force from positive to negative that have to be employed are so rapid that no body large enough to be easily visible and electrified to a reasonable extent could be expected to move sufficiently to be visibly disturbed. It is possible that we may find some way of detecting the vibrations hereby given to the electrified ions in an electrolyte; and it has recently been stated that waves originated electrically shake the elements in sensitive photographic films sufficiently to cause changes that can be developed. The other action of electric force is to produce an electric current in a conductor and a resultant electrification of the conductor. Two effects due to this action have actually been used to detect the existence of the wave of electric force sent out by a body alternately electrified positively and negatively. One of these is the heating of the conductor by the current. Several experimenters have directly or indirectly used this way of detecting the electric force. The other way, which has proved so far the most sensitive of all, has been to use the electrification of the conductor to cause a spark across an air-space. This is the method Hertz originally employed. *A priori*, one would not have expected it to be a delicate method at all. It takes very considerable electric forces to produce visible sparks. On the other hand, the time the force need last in order to produce a spark is something very small indeed, and hitherto it has not been possible to keep up the alternate electrifications for more than a minute fraction of a second, and this is the reason why other apparently more promising methods have failed to be as sensitive as the method of producing sparks. If two conductors be placed very close to one another in such a direction that the electric force is in the line joining them, their near surfaces will be oppositely electrified when the electric force acts on them, and we may expect that, if the force be great enough, and the surfaces near enough, an electric spark will pass from one to the other. This is roughly the arrangement used by Hertz to detect whether there are loops and nodes between the originator of the waves and the reflector.

Now arises the problem of how to electrify the body alternately positively and negatively with sufficient rapidity. How rapid is "with sufficient rapidity"? To answer this we must form some estimate of how rapidly we may expect the waves to be propagated. According to Maxwell's theory, they should go at the same rate as light, some 300 million of metres per second, and it is evident that if we are going to test Maxwell's theory we must make provision for sufficiently rapid electric vibrations to give some result if the waves are propagated at this enormous rate. The distance from a node to a node is half the distance a wave travels during a vibration. If we can produce vibrations at the rate of 300 million per second, a wave would go 1 metre during a vibration, so that, with this enormous rate of alternation, the distance from node to node would be 50 cm. We might expect to be able to work on this scale very well, or even on ten times this scale, *i.e.* with alternations at the rate of 30 million per second, and 5 metres from node to node, but hardly on a much larger scale than this. It almost takes one's breath away to contemplate the production of vibrations of this enormous rapidity. Of course they are very much slower than those of light: these latter are more than a million times as rapid; but 300 million per second is enormously more rapid than any audible sound, about a thousand times as fast as the highest audible note. A short bar of metal vibrates longitudinally very fast, but it would have to be about the thousandth of a centimetre long, in order to vibrate at the required rate. It would be almost hopeless by mechanical means to produce electric alternations of this frequency. Fortunately there is an electric method of producing very rapid alternate electrifications. When a Leyden jar is discharged through a wire of small resistance, the self-induction of the current in this wire keeps the current running after the jar is discharged, and recharges it in the opposite direction, to immediately discharge back again, and so on through a series of alternations. This action is quite intelligible on the hypothesis that electrification consists in a strained condition of the ether, which relieves itself by means of the conductor. Just as a bent spring or other strained body, when allowed suddenly to relieve itself, relieves itself in a series of vibrations that gradually subside, similarly the strain of the ether relieves itself in a series of gradually subsiding vibrations. If the spring while relieving itself has to overcome frictional resistance, its vibrations will rapidly subside; and if the friction be sufficiently great, it will not vibrate at all, but will gradually subside into its position of equilibrium. In the same manner, if the resistance to the relief of the strain of the medium, which is offered by the conducting wire, be great, the vibrations will subside rapidly, and if the resistance of the wire be too great, there will not be any vibrations at all. Of course, quite independently of all frictional and viscous resistances, a vibrating spring, such as a tuning-fork that is producing sound-waves in the air which carry the energy of the fork away from it into the surrounding medium, will gradually vibrate less and less. In the same way, quite independently of the resistance of the conducting wire, we must expect that, if a discharging conductor produces electric waves, its vibrations must gradually subside owing to its energy being gradually transferred to the surrounding medium. As a consequence of this the time that a Leyden jar takes to discharge itself in this way may be very short indeed. It may perform a good many oscillations in this very short time, but then each oscillation takes a very very short time. To get some idea of what quantities we are dealing with, consider the rates of oscillation which would give wave-lengths that were short enough to be conveniently dealt with in laboratories. 300 million per second would give us waves one metre long; consider what is meant by 100 million per second. We may get some conception of it by calculating the time corresponding to 100 million seconds. It is more than 3 years and 2 months. The pendulum of a clock would have to oscillate 3 years and 2 months before it would have performed as many oscillations as we require to be performed in one second. The pendulum of a clock left to itself without weights or springs to drive it, and only given a single impulse, would practically cease to vibrate after it had performed 40 or 50 vibrations, unless it were very heavy, *i.e.* had a great store of energy or were very delicately suspended, and exposed only a small resistance to the air. A light pendulum would be stopped by communicating motion to the air after a very few vibrations. The case of a Leyden jar discharge is more like the case of a mass on a spring than the case of a pendulum, because in the cases of the Leyden jar there is nothing quite analogous to the way in which the earth pulls the pendulum: it is the elasticity of the ether that causes the electric currents in the Leyden jar discharge, just as it is the elasticity of the spring that causes the motion of the matter attached to it in the case of a mass vibrating on a spring. It is possible to push this analogy still further. Under what conditions would the spring vibrate most rapidly? When the spring was stiff and the mass small. What is meant by a spring being stiff? When a considerable force only bends it a little. This corresponds to a considerable electric force only electrifying the Leyden jar coatings a little, *i.e.* to the Leyden jar having a small capacity. We would consequently expect that the discharge of a Leyden jar with a small capacity would vibrate more rapidly than that of one with a large capacity, and this is the case. In order to make a Leyden jar of very small capacity we must have small conducting surfaces as far apart as possible, and two separate plates or knobs do very well. The second condition for rapid vibration was that the mass moved should be small. In the case of electric currents what keeps the current running after the plates have become discharged and recharges them again is the so-called self-induction of the current. It would be well to look upon it as magnetic energy stored up in the ether around the current, but whatever view is taken of it, it evidently corresponds to the mass moved, whose energy keeps it moving after the spring is unbent and rebends the spring again. Hence we may conclude that a small self-induction will favour rapidity of oscillation, and this is the case. To attain this we must make the distance the current has to run from plate to plate as short as possible. The smaller the plates and the shorter the connecting wire the more rapid the vibrations; in fact, the rapidity of vibration is directly proportional to the linear dimensions of the system, and for the most rapid vibrations two spherical knobs, one charged positively and the other negatively, and discharging directly from one to the other, have been used. Hertz in his original investigations used two plates about 40 cm. square, forming parts of the same plane, and separated by an interval of about 60 cm. Each plate was connected at the centre of the edge next the other plate with a wire about 30 cm. long, and terminating in a small brass knob. These knobs were within 2 or 3 mm. of one another, so that when one plate was charged positively and the other negatively they discharged to one another in a spark across this gap. An apparatus about this size would produce waves 10 or 12 metres long, and its rate of oscillation would be about 30 million per second. As the vibration actually produced by these oscillators seems to be very complex, the rate of oscillation can only be described as "about" so and so. In a subsequent investigation Hertz employed two elongated cylinders about 15 cm. long and about 3 cm. in diameter, terminated by knobs about 4 cm. in diameter, and discharging directly into one another. Such an oscillator produces waves from 60 to 70 cm. long, and, consequently, vibrations at the rate of between 400 and 500 million per second. Most other experimenters have used oscillators about the same dimensions as Hertz's larger apparatus, as the effects produced are more energetic; but many experiments, especially on refraction, require a smaller wave to be dealt with, unless all the apparatus used be on an enormous scale, such as could not be accommodated in any ordinary laboratory. When we are thus aiming at rapid rates of vibration, it must be recollected that we cannot at the same time expect many vibrations after each impulse. If we have a stiff spring with a small weight arranged so as to give a lot of its energy to the surrounding medium, we cannot expect to have very much energy to deal with, nor many vibrations, and, as a matter of fact, we find that this is the case. The total duration of a spark of even a large Leyden jar is very small. Lord Rayleigh has recently illustrated this very beautifully by his photographs of falling drops and breaking bubbles. We cannot reasonably expect each spark to have more than from 10 to 20 effective oscillations, so that, even in the case of the slower oscillator, the total duration of the spark is not above a millionth of a second. It is very remarkable that the incandescent air, heated to incandescence by the spark, should cool as rapidly as it does, but there is conclusive evidence that it remains incandescent after the spark proper has ceased, and consequently lasts incandescent longer than the millionth of a second. What is seen as the white core of the spark may not last longer than the electric discharge itself, and certainly does not do so in the case of the comparatively very slowly oscillating sparks that have been analyzed into their component vibrations by photographing them on a moving plate. The incandescent air remaining in the path of such discharge is probably the conducting path through which the oscillating current rushes backwards and forwards. Once the air gap has been broken through, the character of the air gap as an opponent of the passage of electricity is completely changed. Before the air gap breaks down, it requires a considerable initial difference of electric pressure to start a current. Once it has been broken down, the electric current oscillates backwards and forwards across the incandescent air gap until the whole difference of electric pressure has subsided, showing that the broken air gap has become a conductor in which even the feeblest electric pressure is able to produce an electric current. If this were not so, Leyden jars would not be discharged by a single spark. All this is quite in accordance with what we know of air that is, or even has lately been, incandescent: such air conducts under the feeblest electric force. All this is most essential to the success of our oscillator. Only for this valuable property of air, that it gives way suddenly, and thenceforward offers but a feeble opposition to the rapidly alternating discharge, it would have been almost impossible to start these rapid oscillations. If we wish to start a tuning-fork vibrating, we must give it a sharp blow: it will not do to press its prongs together and then let them go slowly: we must apply a force which is short-lived in comparison with the period of vibration of the fork. It is necessary, then, that the air gap must break down in a time short compared with the rate of oscillation of the discharge; and when this is required to be at the rate of 400 million per second, it is evident how very remarkably suddenly the air gap breaks down. From the experiments themselves it seems as if any even minute roughnesses, dust, &c., on the discharging surface, interfered with this rapidity of breakdown: it seems as if the points spluttered out electricity and gradually broke down the air gap, for the vibrations originated are very feeble unless the discharging surfaces are kept highly polished: gilt brass knobs act admirably if kept polished up every ten minutes or so. One of the greatest desiderata in these experiments is some method of making sure that all the sparks should have the same character, and be all good ones.

(*To be continued.*)

THE ROYAL SOCIETY SELECTED CANDIDATES.

The following fifteen candidates were selected on Thursday last (April 30), by the Council of the Royal Society, to be recommended for election into the Society. The ballot will take place on June 4, at 4 p.m. We print with the name of each candidate the statement of his qualifications.

William Anderson,

V.-P. Inst. M.E. M.I.C.E. Consulting Engineer, Royal Agricultural Society of England. Pupil of the late Sir William Fairbairn, F.R.S. Member of the firm of Messrs. Courtney and Stephens, Engineers, of Dublin, from 1855 to 1864. President, in 1863, of the Inst. of Civil Engineers of Ireland, to which Society he communicated important papers:—"On the Theory of Braced Girders;" "The Strength of Railway Bridges of Small Span, and the Cross-beams of Large Bridges;" and other subjects. Between 1872 and 1885, communicated many important papers to the Inst. of Civil Engineers, *e.g.*, "Experiments on Sugar Manufacture, in Upper Egypt, by the Sulphurous Acid Process;" "Experiments and Observations on the Emission of Heat by Hot-water Pipes;" and "Purification of Water on the Large Scale by Agitation with Iron" (being a process successfully elaborated by him, and applied at the Antwerp Waterworks, &c). Received the Telford Medal and the James Watt Gold Medal of the Inst. C.E. Author of a Lecture on "The Generation of Steam," being one of the "Heat Series" of Special Lectures delivered at the Inst. C.E.; of a Text-book on "The Conversion of Heat into Useful Work," being the substance of a course of Lectures delivered at the Society of Arts under the "Howard Trust"; of a paper on "New Applications of the Mechanical Properties of Cork," communicated as a Lecture to the Royal Institution; and of various papers communicated to the Inst. of Mechanical Engineers, the Royal Agricultural Society, &c. Distinguished for the ability with which he has applied his intimate knowledge of the science of heat, and other cognate sciences, to the practical requirements of the engineer.

Frederick Orpen Bower, D.Sc. (Camb.),

F.L.S., F.R.S.E. Regius Professor of Botany in the University of Glasgow. Distinguished for his researches in histological and morphological botany. Author (in conjunction with Prof. S. H. Vines, F.R.S.) of "A Course of Practical Instruction in Botany," and of the following papers, amongst others:—On the Development of the Conceptacle in Fucaceæ" (*Quart. Journ. Micros. Sci.*, 1879); "On the Germination of *Welwitschia*" (*ibid.*, 1880); "On the Further Development of *Welwitschia*" (*ibid.*, 1881); "On the Germination and Embryogeny of *Gnetum Gnemon*" (*Quart. Journ. Micros. Sci.*, 1882); "On the Structure of the Stem of *Rhynchopetalum montanum*" (Journ. Linn. Soc., 1883); "On the Comparative Morphology of the Leaf in Vascular Cryptogams and Gymnosperms" (Phil. Trans., 1884); "On the Apex of the Root of *Osmunda* and *Toaia*" (*Quart. Journ. Micros. Sci.*, 1884); "On Apospory in Ferns" (Journ. Linn. Soc., 1884); "On the Development and Morphology of *Phylloglossum Drummondii*" (Phil. Trans., 1885); "On Apospory and Allied Phenomena" (Trans. Linn. Soc., 1887); "On the Limits of the Use of the Terms Phyllome and Caulome" (*Annals of Bot.*, 1887); "On the Modes of Climbing in the Genus *Calamus*" (*ibid.*); "On some Normal and Abnormal Developments of the Oophyte in Trichomanes" (*ibid.*); "*Humboldtia laurifolia* as a Myrmekophilous Plant" (Trans. Phil. Soc. Glasg.); "The Comparative Examination of the Meristems of Ferns as a Phylogenetic Study" (*Annals of Bot.*, 1889); "On the Morphology of the Leaf of Nepenthes" (*ibid.*); "On Antithetic as distinct from Homologous Alternation of Generations in Plants" (*ibid.*, 1890). Translator (in conjunction with Dr. D. H. Scott) of "Comparative Anatomy of the Phanerogams and Ferns," by Anton de Bary (Clarendon Press, 1884).

Sir John Conroy, Bart., M.A.,

F.C.S. Lecturer on Physics and Chemistry, Keble College, Oxford. An assiduous Student of Experimental Science, and author of the following papers:—"On the Dioxides of Calcium and Strontium" (Journ. Chem. Soc., 1873); "On the Polarization of Light by Crystals of Iodine" (Proc. Roy. Soc., 1876); "Absorption-Spectra of Iodine" (Proc. Roy. Soc., 1876); "On the Light reflected by Potassium Permanganate" (*Phil. Mag.*, 1878); "The Distribution of Heat in the Visible Spectrum" (*Phil. Mag.*, 1879); "Experiments on Metallic Reflexion" (Proc. Roy. Soc., 1871, 1879, 1883).

Daniel John Cunningham, M.D. (Edin.),

M.D. (Dublin), F.R.C.S.I., F.R.S.E., F.Z.S., Professor of Anatomy, University of Dublin. Distinguished both as a teacher and original inquirer. Examiner in Anatomy in the Universities of London, Edinburgh, and Dublin. Member of Council, Royal Irish Academy. Vice-Pres. Zoological Society, Ireland. Vice-Pres. Anatomical Society of Great Britain and Ireland. Author of numerous anatomical memoirs in journals and publications of scientific societies. More especially may be mentioned—"Report on the Anatomy of the Marsupialia" (*Challenger* Report, Part 16); "The Lumbar Curve in Man and Apes," forming Cunningham Memoir, No. 2, published by the Royal Irish Academy, 1886; "The Spinal Nervous System of the Porpoise and Dolphin" (*Journ. Anat. Physiol.*, 1876). Author of a Text-book of Practical Anatomy.

George Mercer Dawson, D.Sc.,

F.G.S., A.R.S.M., F.R.S.C. Assistant Director, Geological Survey of Canada. Much important and valuable work, more especially in geology and ethnology, as in the following summary statement. During his thirteen years of service on the Geol. Survey (Canada) has been chiefly engaged in working out the Geology of the North-West Territory and British Columbia. Placed in charge of the Yukon Expedition, 1887. Author of numerous papers, chiefly geological, but including geographical, ethnological, and other observations, published in the Quart. Journ. Geol. Soc., Trans. Roy. Soc. Canada, *Canadian Naturalist*, &c. These deal more especially with the superficial geology of the regions explored, but some describe Foraminifera and other microscopic organisms. Author of fifteen reports published by the Geological Survey of Canada, and joint author (with Dr. Selwyn) of a Descriptive Sketch of the Physical Geography and Geology of Canada, and (with Dr. W. F. Tolmie) of Comparative Vocabularies of the Indian Tribes of British Columbia.

Edwin Bailey Elliott, M.A.,

Fellow of Queen's College, Oxford. Vice-President of the London Mathematical Society. Mathematical Lecturer of Queen's and Corpus Christi Colleges. Distinguished as a Mathematician and original investigator in various branches of mathematical research. Author of the following papers:—"Generalization of Prevost and Lhuilier's Theorem in Chances" (*Ed. Times*, vol. xxxv.); "On Normals to Envelopes" (*Mess. of Math.*, vol. ix. p. 85); "On Multiple Definite Integrals" (Lond. Math. Soc. Proc., vol. viii., pp. 35, 146); "Kinematics on a Sphere" (*ibid.*, vol. xii., p. 47); "Multiple Frullanian Integrals" (*ibid.*, vol. xv., p. 12; Small Motions of Systems with One Degree of Freedom" (*Mess. of Math.*, vol. xv., p. 38); "The Linear Partial Differential Equations satisfied by Pure Ternary Reciprocants" (Lond. Math. Soc. Proc., vol. xviii., p. 142); "On the Interchange of the Variables in certain Linear Differential Operators" (Abstract, Roy. Soc. Proc., vol. xlvi., p. 358 [ordered to be printed in the Phil. Trans.]); and eighteen other papers printed in the London Mathematical Society's Proceedings and elsewhere between the years 1875 and 1890.

Percy Faraday Frankland, B.Sc.,

A.R.S.M., Ph.D. Professor of Chemistry. Formerly Senior Demonstrator in the Chemical Laboratory of the Normal Schools of Science, South Kensington. Author of upwards of twenty original papers in the Phil. Trans. and Proc. Roy. Soc., in the Journals of the Chem. Soc., the Soc. of Chem. Industry, &c. Known for his researches on Bacteriology and on the Chemical Aspects of Fermentation.

Percy C. Gilchrist,

A.R.S.M. Metallurgist. Distinguished as a Metallurgist, especially in connection with the manufacture of iron and steel. In association with the late Mr. S. G. Thomas he greatly advanced metallurgical practice by the introduction of a process which enables iron to be dephosphorized on a large scale. The process, which is known as the "Basic" process, possesses more than national importance, and its value has been universally recognized. It has further been shown that the slag, which is a product of the Basic process, contains phosphorus in a form which can be readily assimilated by vegetation. One result of his metallurgical work has thus been to substantially benefit agriculture, as more than half a million tons of basic slag are now used annually as a fertilizer. He is the author of numerous papers published in the Journal of the Iron and Steel Institute and elsewhere.

William Dobinson Halliburton, M.D., B.Sc.,

Assistant Professor of Physiology in University College, London. Has during the past four years devoted his entire time to research work in, and teaching of Physiology, especially the chemical side of that science. Has published the following, among other communications:—"On the Proteids of Serum" (Proc. Roy. Soc., and *Journ. of Physiol.*, 1884); "On the Chemical Composition of Invertebrate Cartilage" (Proc. Roy. Soc., 1885, and *Quart. Journ. Micros. Sci.*); "On the Blood of Crustacea" (*Journ. of Physiol.*, 1885, and in a Report to the Scottish Fisheries Board); "On Hæmoglobin and Methæmoglobin Crystals" (*Brit. Med. Journ.*, 1886, and Proc. Physiol. Soc.); "On the Blood-proteids of Lower Vertebrates" (*Journ. of Physiol.*, 1886); "On the Coagulation of Myosin" (Prelim. Communication to Physiol. Soc., 1887).

Oliver Heaviside,

Learned in the science of electro-magnetism, having applied higher mathematics with power and success to the developments of Maxwell's theory of electro-magnetic wave propagation, and having extended our knowledge of facts and principles in several directions and into great detail. He is the author of the following papers among many others:—"On Electro-magnetic Induction and its Propagation" (48 parts, 1885–87, in the *Electrician*); "The Induction of Currents in Cores" (15 parts, 1884–85); "Some Electrostatic and Magnetic Problems" (5 parts, 1883); "Current Energy" (19 parts, 1883–84); "On the Electro-magnetic Effects due to the Motion of Electrification through a Dielectric" (*Phil. Mag.*, 1889); "The General Solution of Maxwell's Equations" (*Phil. Mag.*); "On Electro-magnetic Waves" (6 parts, *Phil. Mag.*, 1888); "On Resistance and Conductance Operators" (*Phil. Mag.*, 1887); "On the Self-induction of Wires" (7 parts, *Phil. Mag.*, 1886–87); "On the Electro-magnetic Wave Surface" (*Phil. Mag.*, 1885); "On the Electro-magnetic Effect of a Moving Charge"; "The Deflection of an Electro-magnetic Wave by Motion of the Medium"; "On the Working of Cells with Condensers" (*Phil. Mag.*, 1874); "On the Extra Current" (1876); "On the Speed of Signalling through Heterogeneous Telegraph Circuits" (*ibid.*, 1877); "On the Effect of Faults on the Speed of Working Cables"; "On Electromagnets" (Journ. Soc. Tel. Eng.); "On Induction between Parallel Wires" (*ibid*).

John Edward Marr, M.A. (Cantab.),

F.G.S. Fellow and Lecturer of St. John's College, Cambridge, and University-Lecturer in Geology. First Class Nat. Sci. Tripos, 1878; Sedgwick Prizeman, 1883; Examiner for the Nat. Sci. Tripos, 1886–87. Secretary of the Geological Society, 1888. Author of the following:—"Fossiliferous Cambrian Slates near Carnarvon" (Quart. Journ. Geol. Soc., 1876); "On Phosphatized Carbonate of Lime at Cave Ha" (*Geol. Mag.*, 1876); "On some well-defined Life-zones in the lower part of the Silurian of the Lake District" (Quart. Journ. Geol. Soc., 1878); "On the Cambrian and Silurian Rocks of the Dee Valley" (*ibid.*, 1880); "On the Pre-Devonian Rocks of Bohemia" (*ibid.*, 1880); "On some Sections of the Lower Palæozoic Rocks of the Craven District" (Proc. Yorks. Geol. Soc., 1882, and Brit. Assoc., 1881); "The Classification of the Cambrian and Silurian Rocks" (*Geol. Mag.*, 1881); "On the Cambrian and Silurian Rocks of Scandinavia" (Quart. Journ. Geol. Soc., 1882); "Origin of the Archæan Rocks" (*Geol. Mag.*, 1883); "The Classification of the Cambrian and Silurian Rocks" (Sedgwick Prize Essay, 8vo, Cambridge, 1883); "The Earth History of the Remote Past compared with that of Recent Times" (8vo, Cambridge, 1886); "The Lower Palæozoic Rocks near Settle" (*Geol. Mag.*, 1887); "The Work of Ice Sheets" (*ibid.*); "Glacial Deposits of Sudbury" (*ibid.*); "On some Effects of Pressure on the Devonian Sedimentary Rocks of North Devon" (*ibid.*, 1888); "The Lower Palæozoic Rocks of the Fichtelgebirge" (*ibid.* 1889); "The Metamorphism of the Skiddaw Slates" (Brit. Assoc., 1889). Joint-papers:—"The Lower Palæozoic Rocks of the Neighbourhood of Haverfordwest" (Quart. Journ. Geol. Soc., 1885); "The Stockdale Shales" (*ibid.*, 1888).

Ludwig Mond,

F.I.C. President of the Society of Chemical Industry, V.-P. Chem. Soc. Distinguished technical chemist and inventor. Has made important additions to chemical industrial processes and products, especially with reference to the alkali industry, having improved the mode of manufacture of carbonate of soda, caustic soda, hydrochloric acid, chlorine, ammoniacal products, and gas generating furnaces, &c. In 1863 he developed what is known as the "Mond Process of Sulphur Recovery from Alkali Waste," and has since that date devoted himself to the introduction and development of the ammonia soda process of alkali manufacture into England. Author of various papers in Rept. Brit. Assoc., Journ. Soc. Chem. Ind.

William Napier Shaw, M.A.,

Fellow of Emmanual College, Cambridge. Was nominated by Lord Rayleigh as one of the Demonstrators of Physics in the Cavendish Laboratory at Cambridge. He held that position from 1880 to 1887, and he has since continued his connection with the Laboratory as University Lecturer in Physics. His knowledge of the manner in which the teaching of Physics is conducted in the great German Universities (acquired at Berlin under Helmholtz) enabled him to bear an important part in the organization of the laboratory. A considerable part of the success of the Cambridge School of Physics is due to his exertions, backed by his knowledge of Physics. Author of numerous books and papers, of which the following are especially worthy of notice:—"Practical Physics" (jointly with Mr. Glazebrook), Longmans, 1885; "Practical Work in the Cavendish Laboratory," University Press, 1886; "Faraday's Law of Electrolysis with reference to Silver and Copper," Rept. Brit. Assoc., 1886; "Electrolysis" and "Pyrometer," "Encyc. Brit."; "On Vaporimeters," &c., Rept. to the Meteorol. Council, 1884; "On Hygrometric Methods, Part I.," Rept. to the Meteorol. Council, printed in Phil. Trans.

Silvanus Phillips Thompson, D.Sc. (Lond.),

Principal and Professor of Physics in the City and Guilds of London Technical College, Finsbury; formerly Professor of Experimental Physics in University College, Bristol. Author of many papers published in the Proceedings, &c., Royal Society, Physical Society, Institution of Electrical Engineers, Society of Arts, and British Association, including the following:—"The Theory of the Magnetic Balance" (Proc. Roy. Soc., 1884); "Electro-deposition of Alloys" (*ibid.*, 1887); "Subjective Interference of Sound" (*Phil. Mag.*, 1887); "Opacity of Tourmaline Crystals" (*ibid.*, 1881); "The Meaning of the Constant in Bernouilli's Law of the Lifting Power of Magnets" (*Phil. Mag.*, 1888); "Development of the Mercurial Air Pump" (Journ. Soc. Arts, 1887); "The Influence Machine from 1788 to 1888" (Journ. Soc. Telegr. Engin., 1888). Author of a treatise on "Dynamo-Electric Machinery" (3rd edit., 1888), and of an elementary text-book of Electricity and Magnetism (43rd thousand, 1889), which has gone through many English and several foreign editions. Originator of improvements in polarizing prisms, in the method of adjusting resistance coils, and in sundry electrical apparatus. Member of Council of the Physical Society, and of the Institution of Electrical Engineers. Distinguished for his acquaintance with the science of electricity, more particularly in its experimental and technical aspects.

Thomas Henry Tizard, Staff-Commander, R.N., H.M.S. *Triton*,

F.R.G.S. Distinguished as a Hydrographical Surveyor and Marine Meteorologist. Has been employed for 25 years in the Naval Surveying Service. In China, Mediterranean, and Red Seas, 1862–72. Senior Assistant-Surveyor in the *Challenger* Expedition, 1872–76. Prepared the reports on the sea temperatures, and on the meteorological observations obtained under his own superintendence during the voyage (*Challenger* Report, vol. ii.); Joint Author of vol. i. *Challenger* Report, contributing the hydrographical portion of the Narrative of the Voyage. Has since served for nine years in charge of surveys on the coasts of the United Kingdom; now employed in command of H.M.S. *Triton*. Has contributed a paper to the Royal Society on the exploration of the Faeroe Channel (Proc. Roy. Soc., vol. xxxv. pp. 202–26; and on the meteorology of Japan, to the Meteorological Council (Official Publication, No. 28).

THE ENDOWMENT OF RESEARCH IN FRANCE.

AT the meeting of the Paris Academy of Sciences on April 27, the Secretary read the following extract from the will of the late M. Cahours:—

"I have frequently had the opportunity of observing, in the course of my scientific career, that many young men, distinguished and endowed with real talent for science, saw themselves obliged to abandon it because at the beginning they found no efficacious help which provided them with the first necessities of life and allowed them to devote themselves exclusively to scientific studies.

"With the object of encouraging such young workers, who for the want of sufficient resources find themselves powerless to finish works in course of execution, and in remembrance of my beloved children, who also would walk in a scientific path at the moment when death takes me from them, I bequeath to the Academy of Sciences, which has done me the honour to admit me into its fraternity, a sum of one hundred thousand francs.

"I desire that the interest of this sum may be distributed every year by way of encouragement to any young men who have made themselves known by some interesting works, and more particularly by chemical researches.

"In order to assure this preference, independently of the express recommendation that I make here to my successors, I wish that, during at least twenty-five years after the commencement of the interest payable to the Academy, three members at least of the Chemistry Section may take part each year in a Commission of five members charged by the Academy to distribute the prizes. I express further the formal desire that this choice should fall, as far as possible, on young men without fortune not having salaried offices, and who, from the want of a sufficient situation, would find themselves without the possibility of following up their researches.

"These pecuniary encouragements ought to be given during several years to the same young men, if the Commission thinks that their productions have a value which permits such a favour.

"Nevertheless, in order that the largest number of young workers may participate in the legacy I institute, I desire that the encouragements may cease at the time when the young *savants* who have enjoyed them obtain sufficiently remunerative positions."

M. Janssen then made the following remarks:—

"The legacy which has been made to the Academy, by our very eminent and very regretted *confrère*, appears to me to have considerable import not only by its importance, but especially by the way that it opens, and the example that it affords, to all those who hereafter may desire to encourage the sciences by their liberality.

"M. Cahours, whose sure judgment and long experience enabled him to know the most urgent necessities of science, had, like most of us, become convinced of the necessity of introducing a new form in the institution of scientific recompenses.

"Our prizes will always continue to meet a great and noble necessity; their value, the difficulty of obtaining them, and the *éclat* they take from the illustriousness of the body which awards them, will make them always the highest and most envied of recompenses.

"But the value, also, of the works it is necessary to produce in order to lay claim to them prohibits the research to beginners. It is a field that is only accessible to matured talents.

"But, besides those *savants* who have already an assured career, there are many young men endowed with precious aptitudes, and directed by their inclination to pure science, but turned very often from this envied career by the difficulties of existence, and taking with regret a direction giving more immediate results. And yet, how many among them possess talents which, if well cultivated, might do honour and good to science!

"We must say, however, that it is in leaving their studies that those who wish to devote themselves to pure science experience the most difficult trials, and these difficulties are increased every day by the very rapid advance of the exigencies of life.

"We must find a prompt remedy for this state of things if we do not wish to see the end of the recruitment of science.

"This truth, however, is beginning to be generally felt. The Government has already created institutions, scholarships, and encouragements, which partly meet the necessity. Some generous donors are also working in this manner. I will mention especially the noble foundation of Mdlle. Dosne, in accordance with whose intentions a hall is at this moment being built, where young men, having shown distinguished aptitudes for high administration, the bar, or history, will receive for three years all the means of carrying on high and peaceful studies.

"Let us say, then, plainly, and in speaking thus we only feebly echo the expressions of the most illustrious members of the Academy, that it is by following the way so nobly opened by Cahours that the interests and prospects of science will be most efficaciously served."

NOTES.

A SPECIAL meeting of the Physical Society of London will be held at Cambridge on Saturday, May 9. The members will leave Liverpool Street at 11 a.m., and on arrival at Cambridge will become the guests of the Cambridge members. The meeting will be held in the Cavendish Laboratory at 2.30. The following communications will be read: some experiments on the electric discharge in vacuum-tubes, by Prof. J. J. Thomson, F.R.S.; some experiments on ionic velocities, by Mr. W. C. D. Whetham; on the resistance of some mercury standards, by Mr. R. T. Glazebrook, F.R.S.; on an apparatus for measuring the compressibility of liquids, by Mr. S. Skinner; some measurements with the pneumatic bridge, by Mr. W. N. Shaw. After the meeting members will have an opportunity of seeing the Cavendish Laboratory and other University Laboratories.

THE annual meeting of the Iron and Steel Institute began yesterday, and will continue to-day and to-morrow. It is being held as usual at the Institution of Civil Engineers in Great George Street.

A VALUABLE bequest has been made to the Department of Science and Art by the late Miss Marshall, of 92 Warwick Gardens, Kensington. In addition to a large number of scientific books and instruments which are left for the use of students, a sum of £1000 is bequeathed for the founding of scholarships, or for application in any other way that may be considered best for the advancement of biological science.

THE Queen has approved the appointment of Lord Derby to be Chancellor of the University of London, in the room of the late Lord Granville.

THE death of Prof. Joseph Leidy, in his sixty-eighth year, is announced. He was Professor of Anatomy in the University of Pennsylvania and of Natural History in Swarthmore College; President of the Academy of Natural Sciences of Philadelphia; and Director of the Department of Biology in the University. In a future number we shall give some account of his services to science.

A REUTER'S telegram from New York, dated May 1, announces the death, at Berkeley, California, of Prof. John Le Conte, brother of Mr. Joseph Le Conte, formerly professor of geology and natural history in the University of California.

WE regret to have to announce the death of Captain Cecilio Pujazon, the Director of the Marine Observatory of San Fernando, near Cadiz. He died on April 15, in his fifty-seventh year. Captain Pujazon was well known to the members of the Eclipse Expedition of 1870, who formed the Cadiz party. He came to London to the Conference on Marine Meteorology in 1874.

IN answer to a question put by Mr. H. Fowler in the House of Commons on Monday, Sir W. Hart Dyke said that from the returns already received, in answer to a circular issued by the

Science and Art Department at the end of March last, it appeared that of the fifty county councils and sixty county boroughs in England, sixteen of the former and twenty-five of the latter had already decided to apply the whole of their share of the residue under the Local Taxation (Customs and Excise) Act of 1890 to science and art and technical education. Nine county councils and two county boroughs had made grants varying from "nearly the whole" to a smaller proportion of their share to the same purpose. Twelve county councils and seven county boroughs had the matter under consideration; that is to say, they had appointed committees, and in many cases the committees had recommended the allocation of the whole or the greater part of the residue fund to technical instruction, but their reports had not yet been confirmed by the county or borough councils. With regard to Wales, the question was complicated by the fact that the Welsh Intermediate Education Act included technical instruction, but it appeared that four county councils and one county borough had applied the whole of their share of the residue under the Intermediate Education Act; while two county councils and one county borough had divided their quota between that Act and the Technical Instruction Act. The remaining six county councils had either made no return, or else had the matter under consideration.

THE Council of University College, Bangor, having resolved to make provision in the physical department (Prof. A. Gray) for the study of applied electricity, an 8 horse-power (nominal) compound engine, working up to 24 horse-power, has just been installed by Messrs. Robey and Co., Lincoln. On Saturday last a satisfactory trial of the engine and boiler was made. The equipment includes a special educational Victoria dynamo (capable of being converted at will into a shunt, compound-wound, or series dynamo, without impairing its usefulness for general work), by the Brush Electrical Engineering Co., an alternating dynamo, and a large secondary battery. The electrical measuring instruments are of the latest design, and include a fine composite balance, and electrostatic voltmeter of Sir William Thomson's invention. The equipment forms a valuable addition to the resources of the College for the teaching of pure and applied physical science, and will render it possible to give a very complete course of instruction in electrical engineering, as well as in the general theory of electricity.

THE Philosophical Society of Berlin offers a prize of 1000 marks for the best essay on the relation of philosophy to the empirical science of nature. The essays may be written in German, French, English, or Latin, and must be sent in before April 1, 1893.

THE Italian Meteorological Society has celebrated its twenty-fifth anniversary by erecting a memorial tablet in the mediæval castle of Turin. The founder of the Society, Father Denza, and various notabilities and ladies were present. Father Denza gave a *résumé* of the history of the Society, which now possesses no less than 250 observatories and stations. The ceremony was terminated by the transmission of a telegram to the King, as Honorary President of the Society.

THE Chief Signal Officer of the United States has published Part III. of "Bibliography of Meteorology," comprising titles relating to the general motions of the atmosphere, or "winds," while the important division of "storms" is being prepared for issue as Part IV. The present volume, like its predecessors, is a lithographic reproduction of a copy prepared by means of a type-writer, as funds were not forthcoming for printing the work, and it contains a total of 2000 titles of books and papers dating from the origin of printing to the close of 1881, with a supplement to the close of 1889, and an author index. The work is quite unique, and will be an invaluable aid to the study of the subject treated of.

AN account of the Birmingham School of Medicine, written originally for the information of those members of the medical profession who attended the Birmingham meeting of the British Association in 1890, has now been published separately. The authors are Dr. B. C. A. Windle and Mr. W. Hillhouse. Their intention is to show—and this they do most effectually—that the centre of the Midland district possesses one of the best equipped schools of medicine in the provinces. The interest of the descriptions is greatly increased by reproductions of some photographs.

A FISH and Game Commission, taking evidence on behalf of the Ontario Government, has received many complaints as to the destruction of deer and other depredations by wolves; and all the witnesses agree that the present bounty of £1 paid for each wolf killed should be raised to £2 10*s*. or £3. It has also been shown that, if the game laws are not more strictly enforced, many birds and fur-bearing animals will probably be exterminated.

THE preliminary returns of the recent census operations in India show that the population in British territory is 220,400,000, as against 198,655,600 in the former census, an increase of nearly 22,000,000. The Feudatory States, omitting incomplete returns, which may be taken at about 90,000, have a population of 61,410,000, making a total of 281,900,000, as against 250,700,000 for the same areas at the last census. The returns give Bombay 806,000, Madras 449,000, Calcutta municipal area and port 674,000, and including the suburbs Howrah and Bally, 969,000. At the last census the total for the same area was 847,000. Calcutta municipal area shows an increase of 92,000, and Howrah and Bally an increase of 24,000. The returns from Burmah show that the population of the whole country, excluding the Shan States, is 7,507,063, or 48·8 persons to the square mile. The population of Lower Burmah alone is 4,526,432, or an increase of about 790,000 since 1881.

THE Boston Society of Natural History has issued a pamphlet announcing the completion of the general plans for the formation of zoological gardens and aquaria in Boston, and appealing to the American public for support. The pamphlet is prettily printed and illustrated, and sets forth very effectively the arguments which may be advanced in favour of the scheme.

THE new number of the Journal of the Royal Horticultural Society contains a full report of the Dahlia Conference, held at the Chiswick Gardens on September 23 last; and of the Grape Conference, held in the same Gardens on September 24. The number also contains valuable papers on various other subjects interesting to horticulturists.

THE Trustees of the Indian Museum, Calcutta, have issued an interesting and instructive Report, by Mr. E. C. Cotes, on the locust of North-Western India (*Acridium peregrinum*). The Report sums up the results of an investigation conducted in the entomological section of the Museum. It seems to be established that most of the flights of this locust issue from the region of sand-hills in Western Rajputana. Others, however, invade India from breeding-grounds which probably lie along the Suliman Range, or even, perhaps, in some cases, beyond India's western frontier, in the sandy deserts of Baluchistan, Southern Afghanistan, and Persia, though the reports received from these regions, Mr. Cotes says, are so fragmentary that no very definite conclusions can be formed from them.

THE *New Zealand Journal of Science*, the publication of which was suspended in 1885, has been revived. The first two numbers of the new issue have been sent to us, and if the same general level of excellence can be maintained in future numbers, there ought to be no doubt as to the success of the enterprise. The following are among the papers: on the history of the

Kiwi, by Prof. T. J. Parker; on the breeding habits of the European sparrow in New Zealand, by T. W. Kirk; the humble-bee in New Zealand, by G. M. Thomson; some notes on the occurrence of the trap-door spider at Lyttelton, by R. M. Laing; on the discovery of the nickel-iron alloy Awaruite, by Prof. G. H. F. Ulrich.

In the paper on the humble-bee in New Zealand, Mr. Thomson says that, wishing to find how far these insects are adapting themselves to new flowers in the colony, he has for a considerable time kept a record of the flowers they visit and of those they leave alone. He has noticed them on many species of introduced plants which they never appear to visit in Europe. They seldom approach white flowers; and, with two exceptions, he has never heard of their visiting the flowers of indigenous plants. The exceptions are *Fuchsia excorticata* and the Ngaio (*Myoporum lætum*).

Messrs. R. Etheridge, Jun., and Mr. A. Sidney Olliff have produced in common a paper which forms a valuable addition to the Memoirs of the Geological Survey of New South Wales. The title is "The Mesozoic and Tertiary Insects of New South Wales."

Messrs. Baillière, Tindall, and Cox publish a second edition of Dr. Thomas Dutton's practical treatise on "Sea-Sickness." Sensible readers will at once be favourably impressed by the author's statement that there is "no absolute specific" for this distressing malady.

Messrs. Cassell and Co. have issued Part 31 of their "New Popular Educator," which will be completed in 48 parts. Besides illustrations in the text, there is a carefully prepared page representing coloured reactions characteristic of certain metals, &c.

Mr. T. H. Cornish, of Penzance, has a note in the current number of the *Zoologist* on some remarkably large catches of fish on the Cornish coast. On March 18 last, 12,000 grey mullet, *Mugil capito*, were captured, by means of a draw seine, by the fishermen of Sennen Cove, at Whitsand Bay, Land's End. The fish were of fine quality, one being brought to Mr. Cornish which measured 2 feet in length, 1 foot 3 inches in girth, and weighed 6 pounds 10 ounces. On the 31st of the same month a Lowestoft mackerel driver, fishing some leagues south-west of the Lizard, took 48,000 mackerel. No such catch of mackerel, for one night's fishing, had ever been heard of before at Penzance, and what makes it more extraordinary, says Mr. Cornish, is that it should have taken place in March, when the catches usually average a few hundreds only. Later on in the season, in the fishing west of Scilly, 20,000 to 25,000 is regarded as a heavy catch. The catch sold for £360.

With reference to our note (vol. xliii. p. 521) on an award made by the Japanese Government to Dr. Shohei Tanaka for "the invention of a new musical instrument," Mr. J. W. Goundry, of Gosforth, Newcastle, writes to us that over twenty years ago he patented an arrangement for giving enharmonic intervals in all keys on the ordinary unaltered keyboard, and that he has had both an organ of 31, and a harmonium of 36, sounds per octave, playing Bach's fugues and Handel's choruses, &c., on the system. He claims that, although his patents were very crude and imperfect, they contain at least the germ of a complete solution of the problem of reconciling just intonation with the ordinary manual. "They embody a system of sounds," he says, "which I believe to be theoretically the truest and practically the simplest possible, and which has nowhere else been described."

Ammonium sulphovanadate, $(NH_4)_3VS_4$, has been isolated in large crystals by Drs. Krüss and Ohnmais, and an account of their work, which also includes the preparation of several other sulpho-salts of vanadium, will be found in the latest number of *Liebig's Annalen*. It is well known that when ammoniacal solutions of vanadates are treated with sulphuretted hydrogen a magnificent purple colouration is produced, presumably due to the formation of sulpho-salts. It has not been found possible, however, to obtain such salts by crystallization *in vacuo*. The method of obtaining the ammonium salt now described is as follows:—A stream of sulphuretted hydrogen is led into an ice-cold saturated solution of ammonium metavanadate, NH_4VO_3, in the strongest ammonia. The immediate effect is to produce the violet-red colour, but the colouration soon disappears and a brown solid is precipitated. On continuing the passage of the gas this precipitate slowly redissolves with production again of the deep violet colour. When the re-solution of the precipitate is almost complete the liquid is filtered, and sulphuretted hydrogen again led through the solution. In a short time crystals commence to separate, when the current of gas is stopped and the liquid left to crystallize in a closed vessel. The crystals thus obtained consist of opaque rhombic prisms very much resembling in appearance those of potassium permanganate. The faces are very brilliant and reflect a steel bluish-violet colour with a greenish tint when the reflection is received at a certain angle. They may be washed with absolute alcohol and afterwards with ether, and finally dried *in vacuo*. The mother liquors from the first crystallizations deposit magnificent crystals on being allowed to stand some weeks. The substance may be much more quickly obtained and in larger quantity by substituting either potassium or sodium vanadates for the ammonium vanadate used in the above mode of preparation, as these salts are much more soluble in ammonia than ammonium vanadate. It is somewhat remarkable that in this case pure ammonium sulphovanadate should be obtained, no potassium or sodium sulpho-salts being ever found in the product. The crystals of ammonium sulphovanadate are permanent in dry air, but are slowly decomposed with evolution of sulphuretted hydrogen in moist air. They are readily soluble in water, forming a solution which is coloured intensely violet even when very dilute. A solution containing only one part of the salt in 100,000 parts of water still possesses a beautiful rose-red colour. After a short time this solution decomposes, sulphuretted hydrogen being liberated and the colour changing to brown. When a freshly prepared solution is added to a solution of a salt of the alkaline earthy metals, no precipitate is produced, owing to the solubility of the sulphovanadates of these metals. But in the case of calcium a remarkable deepening of the violet colour is produced. If, for instance, a little calcium chloride is added to a dilute solution possessing a just perceptible rose tint, the colour becomes immediately deep violet, owing to the extreme tinctorial power of the calcium salt.

In our note in vol. xliii. p. 592, upon the preparation among other silicon compounds of silicon chloro-tribromide, $SiClBr_3$, by M. Besson, it was stated that this substance had not been hitherto prepared. We wish to correct this statement. Silicon chloro-tribromide was prepared by Prof. Emerson Reynolds in 1887, and a descriptive note of the work was given in Nature at the time (vol. xxxvi. p. 137).

The additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus* ♀) from India, presented by Mrs. Emily Palmer; two Brazilian Caracaras (*Polyborus brasiliensis*) from Terra del Fuego, a Turkey Buzzard (*Cathartes aura*) from the Falkland Islands, presented by Mr. F. E. Cobb, C.M.Z.S.; two Herring Gulls (*Larus argentatus*), British, presented by Mrs. Attenborough; a Pine Grosbeak (*Pinicola enucleator*), British, presented by Mr. W. H. St. Quintin; a Bennett's Wallaby (*Halmaturus bennetti* ♂) from Tasmania, two Diamond Snakes (*Morelia spilotes*) from Australia, deposited; two Tasmanian Wolves (*Thylacinus* *cynocephalus* ♂ ♀), three Ursine Dasyures (*Dasyurus ursinus* ♂ ♀ ♀) from Tasmania, two Brush Turkeys (*Talegalla lathami* ♂ ♀), four Australian Wild Ducks (*Anas superciliosa*) from Australia, received in exchange; a Black Lemur (*Lemur macaco*), two Persian Gazelles (*Gazella subgutturosa*), born in the Gardens.

THE INSTITUTION OF MECHANICAL ENGINEERS.

ON the evenings of Thursday and Friday of last week, the 30th ult. and the 1st inst., the Institution of Mechanical Engineers held an ordinary general meeting; the President, Mr. Joseph Tomlinson, occupying the chair. There was an attendance of members somewhat in excess of that which is usual at the ordinary meetings of this Institution. There were two items on the programme—namely, a paper on Lancashire boilers, and a further report from the Research Committee on Marine Engine Trials. The discussion of the latter occupied so much time that the boiler paper had to be shelved until next meeting.

The latest steamer upon which the Marine Engine Research Committee has been experimenting is a cargo vessel named the *Iona*. She was built and engined by W. Gray and Co., of West Hartlepool, and is a good modern example of what can be done in fuel economy with triple expansion engines when high speed is not aimed at. This latest report of the Committee should re-establish in some minds the belief in the economy of the marine surface-condensing engine, which had been, so it was thought, rather shaken by the previous labours of the Committee. When on the first trials of the Committee the fuel consumption of the *Meteor*, *Fusi Yama*, and the *Colchester* came out at not less than 2 pounds of coal per indicated horse-power per hour—the *Colchester's* consumption being nearly 3 pounds per hour—it was said, by those who had never believed in the claims of marine engineers, that the bubble was pricked by a trial made by competent and unbiassed persons. It is true the *Tartar's* trial improved on these figures, the coal consumption coming out 1·77 pound per indicated horse-power per hour; still this is some way behind the 1½ pound of which marine engineers had been boasting. The experiments with the *Iona*, now under consideration, have rehabilitated the marine engine as an economical form of steam motor, for there can be no doubt that the engines of that vessel have given off on trial one unit of power per hour for less than the pound and a half of coal, and we have no reason to think that the 1·38 pound shown on the chief engineer's independent trial is not a fair average for sea running when the disturbing element of measuring tanks is omitted.

The *Iona* is a well decked vessel, built in 1889. She has triple expansion engines on three cranks, working a single screw. The vessel is 275·1 feet long, 37·3 feet wide, and 19 feet deep in the hold. Her moulded depth is 21 feet 10 inches, and her coefficient of fineness is 0·765. She has a cellular bottom. Her mean draught in dock before trial was 20 feet 8 inches, but she rose half an inch in salt water, the displacement being 4430 tons. The engines had been freshly overhauled. The trial took place off the east coast, between Robin Hood Bay and Great Yarmouth. The weather was fine throughout. The engines are triple compound surface condensing. The cylinders are placed in the order—intermediate, high, low, going from forward to aft. The cranks rotate in the sequence—high, intermediate, low. The diameters of the cylinders are 21·88 inches, 34·02 inches, and 56·95 inches; the stroke is 39 inches. The high pressure cylinder only is jacketted, steam being taken from the boiler direct. Outside this jacket are the receivers for the intermediate and low pressure cylinders. The jacket steam therefore parts with heat to the high pressure cylinder, and also heats up the steam passing to the two other cylinders. The arrangement is unusual but not new. A feature worth noting in the present day is that the steam distributing valves are all slide valves. Mr. Mudd, the designer of the engines, does not follow the modern fashion of using piston valves, it being his belief that the advantages they offer are not equal to those lost. The surface condenser has 1360 square feet of tube surface. There are two ordinary steel boilers having 42 square feet of grate surface, the total heating surface being 3160 square feet; which is equal to 75·2 times the grate area. It is not to be wondered at that, with this liberal allowance of heating surface, the fuel economy came out very satisfactorily. The total cross-sectional area through the tubes is 18·3 square feet, and the area across the funnel 30·7 square feet. A notable feature about this vessel is that the boilers are worked on forced draught; or rather there is a fan for supplying air to the fires, for a pressure equal to only 0·17 inch of water in the ash pits hardly fulfils the popular notion of forced draught. The steam for driving the fan-engine was supplied from the donkey boiler, and therefore the measurements of quantities in the performance table were not affected by the amount of steam used by the fan. The matter is not one of great importance—the power to drive the fan not being, perhaps, more than the three-hundredth part of the power of the propelling engines; but we question whether it is strictly fair—as comparing the *Iona's* machinery with that of other vessels—not to take the fan-engine steam from the main supply. The boilers in this ship have an extraordinarily large proportion of tube surface as compared to the grate surface, and this would be likely to lead to an insufficiency of draught were the lighter specific gravity of the chimney gases alone depended upon. If, therefore, the aid of the fan has to be brought in, its cost as well as its services should be taken into account. This is looking at the matter from the point of view of taking the total efficiency of the machinery, and Prof. Kennedy might very justly urge that the steam used by the fan would be a disturbing element, and prevent him from properly determining the efficiency of the engines. The fan undoubtedly belongs to the boiler, but not more so than the feed-pumps; all boilers, however, must have feed-pumps, while comparatively few have fan-engines. If ever it comes to be that fan-engines are almost as much matters of course as feed-pumps, it will be convenient to class the former with the engine, but until then it is as well to estimate the steam required for forced draught purposes by itself; still it should be taken into account.

The air from the fans is taken to the furnace through gridiron valves, which close automatically when the furnace-door is opened, so as to prevent a rush of flame into the stokehold. A small jet of air is also admitted through the wet end of the boiler back by a passage made for the purpose. In this way there are two streams of air which meet in the combustion-chamber. There is also a hanging bridge attached to the back tube plate, and depending into the flame box at the back of the bridge. By these arrangements a very thorough mixing of the air and furnace gases is secured; and to this, no doubt, is due the unusually perfect combustion which was obtained on the trial. The small grates give additional space for the mixing and burning of the gases before they enter the tubes, a most desirable feature in boiler design, and one which should do much to put the cylindrical flues of modern high-pressure boilers on an equality, in the matter of combustion, with the rectangular furnaces of the comfortable low-pressure days of the past generation of marine engineers. At the same time we must not forget that a large amount of fuel burnt on a small grate requires a large combustion chamber. It is the volume of gases evolved which has to be considered. It should be stated that the arrangement for forced draught was designed by Mr. J. R. Fothergill, of Hartlepool, engineer superintendent to the firm owning the ship.

It is so difficult to get accurate data upon the weight of marine engines, that we add the figures given in the report:—

	Tons.
Engines alone	94·92
Shafting, tunnel-bearings, and propeller ...	26·59
Engine-room auxiliaries, including donkeys, pipes, platforms, ladders, and gratings ...	12·16
Boilers alone	58·60
Boiler-room auxiliaries, including forced draught gear, smoke-box, uptake, funnel, furnace gear, mountings, stokehold floor, boiler-chocks, and ties	28·49
Water in boilers	35·75
Total	228·22

The coal used was of good quality. The following analysis (as used) will be of interest:—

	Per cent.
Carbon	82·34
Hydrogen	5·47
Moisture	1·94
Ash	2·90
Nitrogen, sulphur, oxygen, &c., by difference ...	7·35
	100·00

The calculated calorific value is 14,830 thermal units per pound, which corresponds to the evaporation of 15·35 pounds of water from and at 212° F. A portion of the coal used was also tested by a Thomson calorimeter, and gave a value of 14,980 thermal units per pound. Thirteen samples of furnace gases were taken over mercury and were analyzed. The following are the means:—

	By volume per cent.	By weight per cent.
Carbonic acid	8·20	12·12
Carbonic oxide	0·00	0·00
Oxygen	11·17	12·01
Nitrogen	80·63	75·87
	100·00	100·00

Chimney temperatures were read every half-hour by a mercury thermometer and by two Murrie pyrometers at 30 feet above the furnace bars. The readings of the three instruments agreed, the average temperature being 452° F. It was a pity that the readings were taken so far from the fires, it being desirable to know the heat of the products of combustion immediately after leaving the heating surface of the boiler. The arrangement, however, was unavoidable, owing to the exigencies of running the ship on her voyage. The measurement of the feed was carried out by means of two tanks in the usual way. An effort was made to determine the quantity of water brought over unevaporated, by the draught of steam. This was done by taking samples of condensed steam from the steam pipe and samples of boiler water, and analyzing them to ascertain the percentage of salt. Unfortunately the apparatus broke down; but from two pairs of analyses made, it was estimated that there was 2·87 per cent. of unevaporated boiler water in the condensed steam. If this were the case with boilers so easily driven as those of the *Iona*, where there could hardly have been any semblance of "priming," as the term is understood by engineers, the quantity of water brought over in small and hardly driven boilers must be enormous. It is a point of the greatest importance in steam-engine economy, and we trust Prof. Kennedy will pursue his investigations in this direction. It also came out during the discussion that the stop valve, or throttle valve, was very much closed during the trial, a fact which should still further have reduced the chance of unevaporated water finding its way into the engines.

Indicator diagrams were taken every half-hour during the trial, and an average set is attached to the report. The power was very evenly distributed between the three cylinders, showing good design of the engines. The total indicated horse-power was 645·4. Diagrams were also taken from the air and circulating pumps. For these interesting and valuable details we must refer our readers to the paper itself, as we are unable to reproduce the diagrams.

The following are some of the chief elements of the trial:—

Date	July 13 and 14, 1890.
Duration of trial	16 hours.
Heating surface, total	3160 square feet.
,, ,, tubes	2590 ,, ,,
Grate area	42 ,, ,,
Total heating surface to grate surface...	75·2 ratio.
Grate area to flue area through tubes...	2·3 ,,
Mean boiler pressure above atmosphere	165·0 lbs. per sq. in.

A long discussion, occupying both evenings of the meeting, followed the reading of the paper, but our account has already extended to such a length that we cannot give a report of it. Perhaps the most interesting point raised was in connection with the closing of the chimney damper, which it appeared was only one-sixth open during the trial. The reason given for this was that in this way heat was prevented from escaping up the chimney. It is difficult to account for such an effect, excepting perhaps to some trifling extent due to minor causes, but several engineers whose opinion is worthy of respect testified that such was the effect in practice. One would think that the escape of heat by the chimney would be governed by the volume of escaping products of combustion with a chimney of any reasonable cross area.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The first Clerk Maxwell Scholarship, for research in Experimental Physics, has been awarded to W. Cassie, M.A., Trinity College.

Mr. H. J. Mackinder, the Reader in Geography at Oxford, is to lecture for the Teachers' Training Syndicate on "The Teaching of Geography," on May 30.

The annual dinner of the Philosophical Society was held in the Combination Room of St. John's College on May 2, Prof. G. Darwin in the chair.

DUBLIN.—Sir Robert Ball begins on Wednesday, the 13th inst., a course of lectures on "The Theory of Screws," in Trinity College, Dublin.

SCIENTIFIC SERIALS.

THE *Quarterly Journal of Microscopical Science* for March contains:—On a new species of Phymosoma, with a synopsis of the genus, and some account of its geographical distribution, by Arthur E. Shipley (Plate xi.). The new species, *P. weldoni*, was found by Prof. Weldon at Bimini Island, the Bahamas; it has no trace of hooks on the introvert; there are two retractors. A synopsis of the twenty-seven species now known is given, but seventeen species are described in Selenka's monograph on the Sipunculidæ. As to the geographical distribution, seventeen species are found in the Malay Archipelago, of which thirteen are endemic, five are found in the Red Sea, four in the Mauritius, and three are found in the West Indies, but *P. lovenii* is found only in the Bergen Fiord.—On the British species of Crisia, by Sidney F. Harmer (Plate xii.). The author thinks that the ovicells furnish satisfactory specific characters; the aperture in the ovicell is also an important character. Specific diagnoses of *C. denticulata*, Lmk., *C. eburnea*, Linn., *C. aculeata*, Hass., and *C. ramosa*, n. sp., are given. Notes are given of the habit of the Zoarium at different seasons, on the mode of branching, and on the breeding-times.—The later larval development of Amphioxus, by Arthur Willey (Plates xiii.–xv.). The author again visited Messina, in the summer of 1890, to complete his studies on the development of the atrial chamber of Amphioxus. As a possible explanation of the asymmetry of the larva, Willey thinks that it can be traced ultimately to the adaptive forward extension of the notochord, being thus a purely ontogenetic phenomenon; the club-shaped gland is shown to be a modified gill-slit.—On the structure of two new genera of earthworms belonging to the Eudrilidæ, and some remarks on Nemertodrilus, by Frank E. Beddard (Plates xvi.–xx.). *Hyperiodrilus africanus*, n. gen. and sp., and *Heliodrilus lagosensis*, n. gen. and sp., found in a Ward case from Lagos, at Kew Gardens.

THE only article of general interest in the *Nuovo Giornale Botanico Italiano* for April is a note on the stigmatic disk of *Vinca major*, by Sig. M. Pitzorno. In the reports of the Italian Botanical Society are short papers by Sig. Baccarini on the secretory system of the Papilionaceæ; on the arrangement of herbaria, by Sig. L. Micheletti; and others of special interest to Italian botanists.

SOCIETIES AND ACADEMIES.

London.

Royal Society, April 16.—"An Attempt to determine the Adiabatic Relations of Ethyl Oxide. Part I. Gaseous Ether." By Prof. W. Ramsay, F.R.S., and E. P. Perman, B.Sc.

The object of the research described in the memoir is the determination of the behaviour of ether in the state of gas approaching towards the state of liquid, when heat is communicated to it, so as to alter its condition adiabatically.

Previous researches by one of the authors in conjunction with Dr. Sydney Young have yielded data regarding the relations of pressure, temperature, and volume of gaseous and of liquid ether from which the values of the isobaric and of the isochoric differentials are obtainable. Such results lead directly to a knowledge of the differences between the specific heats at constant pressure and those at constant volume; and these differences are not constant, but vary with varying volume, pressure, and temperature.

The memoir contains an account of experiments made to determine the ratio between the specific heats at constant pressure and those at constant volume. The velocity of sound in gaseous ether was determined at various temperatures, pressures, and volumes; and by means of the isothermal differentials, and the experimental results for the velocity of sound, the ratios between the two specific heats were calculated. From the differences and the ratios of the specific heats, the values of the specific heats were deduced.

The general conclusion is that, for any constant volume, the specific heat, whether at constant volume or at constant pressure, decreases to a limiting value with rise of temperature, and subsequently increases; and that the change with temperature is more rapid, the smaller the volume.

At large volumes, the specific heats tend towards independence of temperature and volume, while at small volumes the influence of change of temperature and volume is very great.

The authors are at present investigating similar relations for liquid ether.

Zoological Society, April 21.—Prof. W. H. Flower, C.B., F.R.S., President, in the chair.—A communication was read from Lieut.-Colonel Sir Oliver B. C. St. John, R.E., containing notes on a case of a Mungoose (*Herpestes mungo*) breeding during domestication.—Mr. R. E. Holding exhibited and made some remarks on some remarkable horns of Rams of the domestic Sheep of Highland and other breeds.—Messrs. Beddard and Murie exhibited and made remarks on a cancerous nodule taken from the stomach of an African Rhinoceros (*Rhinoceros bicornis*), which had recently died, after living 22 years in the Society's Gardens.—Mr. E. T. Newton read a paper on the structure and affinities of *Trogontherium cuvieri*, basing his remarks principally on a fine skull of this extinct Rodent lately obtained by Mr. A. Savin from the forest-beds of East Runton, near Cromer.—Mr. H. J. Elwes read the first part of a memoir on the Butterflies collected by Mr. W. Doherty in the Naga Hills, Assam, the Karen Hills in Lower Burmah, and in the State of Perak.—Mr. J. J. Lister gave an account of the birds of the Phœnix Islands, Pacific Ocean, as collected and observed during a visit to this group made in H.M.S. *Egeria* in 1889.

May 1.—Sixty-second Anniversary Meeting.—Prof. Flower, F.R.S., President, in the chair.—After the auditors' report had been read, and other preliminary business had been transacted, the report of the Council on the proceedings of the Society during the year 1890 was read by Mr. Sclater, F.R.S., the Secretary. It stated that the number of Fellows on January 1, 1891, was 3046, and that the number of Fellows elected or readmitted in 1890 was 121, being 4 less than the corresponding number in 1889. Since the last anniversary 2 Foreign Members and 11 Corresponding Members had been elected to fill vacancies in those lists. In recognition of the effective protection accorded for sixty years to the Great Skua (*Stercorarius catarrhactes*) at two of its three British breeding stations—namely, in the Island of Unst by the late Dr. Laurence Edmondston and other members of the same family, and in the Island of Foula by the late Dr. Scott, of Melby, and his son, Mr. Robert T. C. Scott—the silver medal of the Society had been awarded to Mrs. Edmondston, of Buness House, as representative of that family, and to Mr. Robert T. C. Scott, of Melby. The total receipts of the Society for 1890 had amounted to £25,059, which, although not quite equal to those of 1889, had exceeded those of 1888 by upwards of £1000, and might be deemed to be satisfactory. The ordinary expenditure for 1890 had been £23,342 6*s.* 11*d.*, which was £659 2*s.* 8*d.* more than the corresponding amount for 1889. Besides this an extraordinary expenditure of £230 4*s.* 6*d.* had been devoted to the material improvement of the Monkey House, which brought up the total expenditure of the year to £23,572 11*s.* 5*d.* The balance brought forward from 1889 was £1242 13*s.* 11*d.*, and this, added to the income received in 1890, gave a total sum of £26,302 11*s.* 9*d.* available for the expenditure of the year 1890. By these means the Council had been enabled, after payment of the ordinary and extraordinary expenditures of the year, not only to devote the usual sum of £1600 to the reduction of the mortgage-debt on the Society's freehold premises (which at present amounted to £5000 only), but also to purchase a sum of £1000 in Consols, in order to form the nucleus of a new reserve fund. The usual scientific meetings had been held during the session of 1890, and a large number of valuable communications had been received upon every branch of zoology. These had been published in the annual volume of Proceedings for 1890, which contained 730 pages, illustrated by 57 plates. Besides this, part x., being the concluding part of the twelfth volume, of the Society's quarto Transactions had been issued. The twenty-sixth volume of the *Zoological Record*, containing a summary of the work done by British and foreign zoologists during the year 1889, had been issued to the subscribers in December last, and had thus been published before the close of the year after that to which it relates. The library had been kept in good working order during the past year, and had been much frequented by working zoologists. A large number of accessions, both by gift and purchase, had been received and incorporated. In the Gardens the only new work carried out in 1890 had been the completion of the improvements of the Monkey House, but a large number of repairs and renewals of the different buildings in the Gardens had been made, and other minor improvements had been carried out. The number of visitors to the Gardens during the year 1890 had been 640,987, the corresponding number in 1889 having been 644,579. The number of school children admitted free in 1890 was 35,935. The number of animals in the Society's collection on December 31 last was 2256, of which 693 were mammals, 1273 birds, and 290 reptiles. Amongst the additions made during the past year, twelve were specially commented upon as of remarkable interest, and in most cases representing species new to the Society's collection. About 28 species of mammals and 20 of birds had bred in the Society's Gardens during the summer of 1890. The report concluded with a long list of the donors and their various donations to the Menagerie during the past year.—A vote of thanks to the Council for their report was moved by Mr. W. H. Hudleston, F.R.S., seconded by Mr. A. J. Scott, and carried unanimously.—The report having been adopted, the meeting proceeded to elect the new Members of Council and the officers for the ensuing year. The usual ballot having been taken, it was announced that Mr. William T. Blanford, F.R.S., Dr. Albert Günther, F.R.S., Mr. E. W. N. Holdsworth, Sir Albert K. Rollit, M.P., and Mr. Howard Saunders, had been elected into the Council in the place of the retiring members, and that Prof. Flower, C.B., F.R.S., had been re-elected President, Mr. Charles Drummond, Treasurer, and Dr. Philip Lutley Sclater, F.R.S., Secretary to the Society for the ensuing year.—The remaining business having been concluded, the President handed the silver medal of the Society to Mr. Thomas Edmondston, who attended on the part of Mrs. Ursula Edmondston, of Buness, Unst, Shetland, and to Mr. A. P. Purves, who attended on behalf of Mr. Robert T. C. Scott, of Melby, Shetland, in recognition of the effective protection accorded by them and their families respectively to the Great Skua at its breeding places in the Shetland Islands.—The proceedings terminated with the usual vote of thanks to the President.

Geological Society, April 22.—Dr. A. Geikie, F.R.S., President, in the chair.—The following communications were read:—Results of an examination of the crystalline rocks of the Lizard district, by Prof. T. G. Bonney, F.R.S., and Major-General C. A. McMahon. The authors, in company with the Rev. E. Hill, spent a considerable part of last August in examining anew those sections in the Lizard district which had any bearing upon the questions raised since the publication of Prof. Bonney's second paper in 1883. They had also the advantage of occasional conference with Mr. Teall and Mr. Fox, whose valuable contributions to the knowledge of the crystalline rocks of this district are well known. That the Lizard serpentines are altered peridotites may be regarded as settled, but doubts have been expressed as to their relation to other associated rocks, and as to the meaning of a streaky or banded structure exhibited by certain varieties. The authors, after re-examination of a large number of sections, feel no doubt of the accuracy of their original view that the peridotite was intruded into the hornblende schists and banded "granulitic" rocks, after these had assumed their present condition. In it they find no signs of any marked pressure-metamorphism, either prior or posterior to serpentinization. They have failed to connect the streaky or banded structure with any foliation or possible pressure-structure in the schists, and they can only explain it as a kind of fluxion-structure, viz. as due to an imperfect blending of two magmas of slightly different chemical composition, anterior to the crystallization of the mass. The Porthalla sections have been examined with especial care, not only because the serpentine is nowhere so conspicuously banded, but also because its intrusive character has been denied, both it and the hornblende schists being ascribed to the alteration of a series of sedimentary rocks of suitable composition. For this view the authors have failed to discover any evidence, and consider it contrary to stratigraphical and petrographical facts. In regard to the genesis of the crystalline schists, which for purposes of reference were divided by Prof. Bonney into a "granulitic," a "hornblendic," and a "micaceous" group, the authors show that in parts of the first the more acid rock breaks through the more basic, as if intrusive, in others they appear to be perfectly interstratified, the one passing backwards and forwards, though rapidly, into the other. But between these extremes, intervals can be found where the two rocks seem as if partially drawn out together. The authors are agreed that certainly one, probably both, of these rocks are igneous, that when the basic rock was solid enough to be ruptured, the acid magma broke into it, and sometimes softened it sufficiently to allow of the two flowing for some little distance together, after which crystallization took place. In regard to the hornblende schists, the authors are not yet satisfied that either fluxion or mechanical crushing will account for every structure which they have examined, and prefer to leave the question, in certain cases, an open one. The most distinctive features of the micaceous group appear due to subsequent earth-movements, so that, though it exhibits some special characteristics, the authors are doubtful whether it is any longer worth while separating it from the hornblende schists. Of the igneous rocks newer than the serpentine, the gabbro has received the closest attention. It exhibits in places (especially in the great dyke-like mass at Carrick Luz) a very remarkable foliation or even mineral banding, which has been claimed as a result of dynamo-metamorphism. The authors bring forward a number of instances to establish the following conclusions:—(*a*) That this foliation occurs most markedly where the adjacent serpentine does not show the slightest sign of mechanical disturbance; (*b*) that it must be a structure anterior to the consolidation of the rock; (*c*) that it sets in and out in a very irregular manner; (*d*) that when it was produced the rock was probably not a perfect fluid. Hence they explain it also as a kind of fluxion structure, produced by differential movements in a mass which consisted of crystals of felspar and pyroxene, floating thickly in a more or less viscous magma. The authors' investigations tend to prove that (*a*) structures curiously simulative of stratification may be produced in fairly coarsely crystalline rocks by fluxioned movements anterior to crystallization; and that (*b*) structures which of late years have been claimed as the result of dynamo-metamorphism subsequent to consolidation must have, in many cases, a like explanation. This is probably the true explanation of a large number of banded gneisses which show no signs of crushing and holocrystalline, but in their more minute structures differ from normal igneous rocks. The authors have seen nothing which has been favourable to the idea that pressure has raised the temperature of solid rocks sufficiently to soften them. A discussion followed, in which Mr. Teall, the Rev. E. Hill, Prof. Hull, the President, General McMahon, and Prof. Bonney took part.—On a spherulitic and perlitic obsidian from Pilas, Jalisco, Mexico, by Frank Rutley.

Royal Microscopical Society, April 15.—Dr. R. Braithwaite, President, in the chair.—Mr. T. Charters White presented three slides of sections of teeth permeated with collodion.—A letter from Mr. J. Aitkin, of Falkirk, was read, on a spot-mirror method of illumination.—An abstract was read of a paper, by Surgeon V. Gunson Thorpe, R.N., on some new and foreign Rotifera found on the West Coast of Africa, and belonging to the genera *Trochosphæra* and *Floscularia*.—Mr. E. M. Nelson exhibited two forms of bull's-eye condenser—one made like Herschel's asplanatic, the other a new and simpler form, being made of two plano-convex lenses. This condenser seemed to answer its purpose admirably, the amount of spherical aberration being only about one-fifth of that which existed in the old form.—Mr. Nelson also read some further notes on Diatom structures as test-objects, which he illustrated by photographs.—Mr. C. Haughton Gill's additional note on the treatment of Diatoms was read, the subject being illustrated by photo-micrographs. Mr. Mayall said the problem Mr. Gill had endeavoured to solve was as to the existence or not of cellular structure in Diatoms extending through their substance, and he sought to demonstrate this by making chemical depositions which would probably fill up the cavities sufficiently to be distinguished by the microscope. Mr. Gill's observations were of great interest, because he had experimented with the definite purpose of testing a special point, thus applying to microscopy what Herschel would have termed an "experiment of inquiry"—a direct questioning of Nature on a point that had hitherto been regarded as almost beyond the sphere of experiment.

PARIS.

Academy of Sciences, April 27.—M. Duchartre in the chair.—The Secretary read an extract from the will of the late M. Cahours, and M. Janssen made some remarks upon the legacies left for the foundation of scholarships (see p. 17).—On the expressions of the pressures in an elastic homogeneous body, by M. H. Resal.—On the theory of elasticity, by M. H. Poincaré.—Researches upon humic substances, by MM. Berthelot and G. André. According to the observations of the authors, the humic substance formed by the action of hydrochloric acid upon cane sugar possesses etheric and anhydric properties, and is comparable in certain respects to the lactones.—On the origin of pus cells and on the *rôle* of these elements in inflamed tissues, by M. L. Ranvier.—On the performance of marine engines and that of screws, and on a geometrical method for calculating the first of these values without a dynamometer, by M. A. Ledieu.—Mica as an invariable dielectric, by M. E. Bouty. The author has previously shown that the capacities of mica condensers vary slightly with the duration of charging. He now finds that mica behaves as an invariable dielectric in a direction normal to the planes of cleavage—that is, the capacity (c) of a lamina of useful surface (ρ) and thickness (e) is represented by the formula $c = \frac{k\rho}{4\pi e}$, where k is a constant. It is remarked that the origin of the large variations of such condensers with duration of charging is the electrolysis of foreign substances contained in the superficial layers.—On an alternate current motor, by MM. Maurice Hutin and Maurice Leblanc.—Quantitative studies on the chemical action of light: first part—measure of physical absorption, by M. G. Lemoine. The action of light upon a mixture of oxalic acid and ferric chloride of various thicknesses and strengths is theoretically and experimentally determined.—Effect of the presence of halides of potassium upon the solubility of the neutral sulphate of potassium, by M. Ch. Blarez. Between 0° and 30° the solubility of K_2SO_4 in water is given in parts per 100 by

$$Q\theta = 8{\cdot}5 + 0{\cdot}12\theta.$$

On adding KCl, or other halide of potassium, at any definite temperature, the K_2SO_4 remaining in solution is given by the expression—

K_2SO_4 dissolved = a constant − the amount of K in added salt;

for any temperature this becomes

$$K_2SO_4 \text{ dissolved at } \theta^\circ = 7{\cdot}5 + 0{\cdot}1417\theta - \text{K of added salt.}$$

The precipitating action of the halides of potassium upon the saturated solution of the neutral sulphate of potassium is *proportional to the equivalent of the added salt*.—On iso-cinchonine, by MM. E. Jungfleisch and E. Léger.—On a hydrocarbon of the terpene series contained in the oils of compressed gas, by MM. A. Étard and P. Lambert. This is a pyropentylene not identical with valylene or pirylene; it polymerizes readily to $C_{10}H_{12}$. Its properties and relations with the terpenes will be given in a subsequent paper.—Researches upon trehalose, by M. Maquenne. Anhydrous trehalose is an oct-atomic alcohol isomeric with the saccharoses, and very near to maltose in chemical constitution; it yields glucose on inversion, and does not fulfil aldehydic functions.—On the constitution of aqueous solutions of tartaric acid, by M. Aignan. The author arrives at the conclusion that tartaric acid exists in aqueous solution in the state expressed by the formula $(C_4H_6O_6)_2$, partially dissociated according to a definite law.—Researches upon the artificial production of hyalite at the ordinary temperature, by M. Stanislaus Meunier.—On the stomachic digestion of the frog, by M. Ch. Contejean. Experimental evidence is given (1) that the pepsin secreted by the œsophagus is more abundant or more active than that of the stomach; (2) that the œsophagean and stomachic pepsins transform coagulated albumin into syntonin, and afterwards into peptone, without passing through the pro-pepsin stage; (3) that the predominance of the action of œsophagean pepsin on stomachic pepsin is especially manifest by the larger quantity of syntonin that it produces.—On the sexual evolution of the trouts of the Pyrenees, by M. A. Cannieu. The metamere of the endodermous layer and of the primitive circulatory system in the post-branchial region of Vertebrata, by M. F. Houssay.—Contribution to the study of the mechanism of urinary secretion, by M. O. van der Stricht. —Reappearance during winter of the starch in ligneous plants, by M. Émile Mer. The researches indicate that in ligneous plants starch is reabsorbed at the end of the autumn, and generated at the beginning of spring. It results from this that the winter, instead of being the season during which the amylaceous reserve is most considerable, is the season during which it is least.—On some points in the anatomy of the vegetative organs of Ophioglossa, by M. G. Poirault. The observations show that the Ophioglossum fungus is never reproduced by spores, but is propagated exclusively by buds on the roots.—On the existence of Diatoms in the lower lands of North France and Belgium, by M. L. Cayeux.—On the proportion of water in corn from different localities, by M. Balland.—On the treatment of phylloxerous vines by carbon bisulphide mixed with vaselines, by M. P. Cazeneuve.

BRUSSELS.

Academy of Sciences, February 7.—M. F. Plateau in the chair.—Micrographical researches on the nature and origin of phosphate rocks, by M. A. F. Renard. The author gives the preliminary results of some researches on the formation of phosphate rocks. The investigation has been especially directed towards the problem of the origin of these rocks, and some important conclusions are arrived at with regard to this point. A lithographic plate, containing magnified representations of nineteen phosphate chalk specimens, accompanies the paper.—The winter of 1890-91, by M. F. Folie. It is remarked that observations at Brussels show that the winter of 1890-91 is one of the severest passed during the last sixty years. Since 1833 seven winters have been of a severity comparable with the last. They are 1837-38, 1840-41, 1844-45, 1846-47, 1854-55, 1870-71, 1879-80. A table is given showing the mean minimum temperature and the mean temperatures experienced during these years. This comparison and a consideration of summer temperatures do not point to any particularly definite facts. The idea that a hot summer succeeds a rigorous winter does not appear to be supported. On the contrary, it appears that the coming summer should be more cold than hot, with the exception of the months of May and August.—On variations in the latitude of a single place, by M. F. Folie. The reality of the variations in latitude deduced from observations made at Berlin, Potsdam, and Prague, are contested on the ground of systematic errors in the formulæ of reduction, due to the assumption that the earth has been considered to move as a solid body, whereas M. Folie believes it to be composed of a fluid nucleus with a solid crust. —Researches on the development of Arachnætis: contribution to the morphology of Cerianthidæ, by M. E. van Beneden.—Researches on the velocity of evaporation of liquids at temperatures below their boiling-points, by M. P. de Heen. The first part of this paper was read at the January meeting. The results are now given of experiments on the variations of the velocity of evaporation with the hygrometric condition of the current employed. The whole of the observations show that the velocity of evaporation, v, of a liquid surface acted on by wind may be expressed by the formula—

$$v = \mathrm{AF}\,(100 - 0{\cdot}88f)\sqrt{\mathrm{V}}$$

where A is a constant, F the tension of the saturated vapour at the temperature of the liquid, and V the velocity of the current. —Determination of the radius of curvature in parallel coordinates, by M. Maurice d'Ocagne.

March 7.—M. Plateau in the chair.—On a curious peculiarity of currents of water, and on one of the causes of sudden floods, by M. G. van der Mensbrugghe. An explanation is given of the fact that in a river the maximum velocity of the current does not occur at the surface, but about three-tenths of the depth below the surface.—Reduction of nitrates by sunlight (second note), by M. Émile Laurent. The author has caused a beam of sunlight to fall upon solutions of nitrates placed in a vacuum, and has found that after a certain time the space contained liberated oxygen, whilst the liquids possessed the characteristic reactions of nitrites. M. Laurent has analyzed the oxygen and nitrites, and finds that the quantity of gas is sensibly proportional to the nitrite formed. As might have been expected, the blue end of the spectrum possesses the most powerful reducing action.—Note on the coagulation of the albumins of the serum of cow's blood, by MM. J. Corin and G. Ansiaux. The authors support the assertion made by Halliburton in 1883, that the albumin of serum ought not to be considered as a single substance, but as a mixture of two or three albuminoids, α, β, and γ, coagulating respectively at temperatures—$\alpha = 73^\circ$ C., $\beta = 77^\circ$ C., and $\gamma = 82^\circ$ C. The blood of man, the dog, pig, rabbit, &c., were known to contain these three substances, and it is now shown that the serum of the cow also contains the paraglobulin α, and the albumins β and γ. Further, it is shown that opalescence and coagulation are not distinct things, but two forms of one and the same phenomenon occurring at the same temperature.—On the curvature of polars with respect to a point on a curve of the nth order, by Prof. C. Servais.—Discovery of a variable star, by M. L. de Ball. An account is given of observations of a variable red star situated in R.A. 20h. 41m. 19s., Decl. $+ 2^\circ\ 2'{\cdot}3$ (1891). The observations extend from September 15, 1890, to January 9, 1891. In this time the magnitude of the star increased from 8·7 to 8. The star is not included in Bermingham's Red Star Catalogue. M. de Ball's observations are only eye-estimations, and have not been made by the aid of a photometer. Further evidence of variability is therefore required.

PRACTICAL GEOLOGY.

Aids in Practical Geology. By Grenville A. J. Cole, F.G.S., Professor of Geology in the Royal College of Science for Ireland. (London: C. Griffin and Co., 1891.)

An Introduction to the Study of Petrology: the Igneous Rocks. By Frederick H. Hatch, Ph.D., F.G.S. (London: Sonnenschein and Co., 1891.)

HOWEVER prophetic may have been the far-seeing premonitions of men in advance of their age in the dim past, and however invaluable may have been the additions made to the superstructure since, it can scarcely be doubted that the foundation-stones of geology were laid by Scotchmen and Englishmen towards the end of the last, and during the earlier part of the present century. And what a charm is there about the story of these sturdy pioneers, not perhaps quite the men whom one would have picked out as most fitted or most likely to become the fathers of a new science. It has about it the elements of a genuine romance. For the early training of few of these men was such as to give a scientific bent to their mind; they did not have what we are pleased to call "the advantage of a scientific education"; it is probable that they never spoke, perhaps never dreamed of, such a phrase as "the scientific method," which we are so fond of formularizing, and on which we plume ourselves somewhat. But in spite of these seeming drawbacks, rather perhaps because with these men genius was allowed to run its spontaneous untrammelled course, they opened out to mankind a domain of knowledge the very outskirts of which had been barely touched upon before. Of shrewd mother-wit were they; too keen of eye to be wrong about their facts; not a few were ardent sportsmen, and the same instinct which led them to ride straight to hounds or patiently and warily to stalk the deer, led them also, as they brushed away minor details, to go direct to main issues, and carried them on, without rest but without haste, through the toils of many a year's steady field-work. With what awe and reverence do we look up to these giants when we pass their achievements in review!

Nor does it one whit impair this feeling of respectful admiration to turn to the other side, and cast a glance at what were their unavoidable shortcomings. They were too hard-headed to be illogical in the matter of straightforward inferences, but it was hardly to be expected that they would escape going astray sometimes when they ventured on recondite speculation. Rough is not the word for their method; incomplete would be nearer the mark, but even that can scarcely be applied when the means at their disposal are taken into account. No one had yet taught the value of the microscope and balance to the geologist; and, when these and other instruments of precision were introduced, there was just a tendency to gird at appliances that had a finnicking look about them to Titans who had so long and so successfully relied on their hammers and their wits.

But by degrees it became clear in Germany, and later on in England, that, though the great main roads of the newly-discovered territory had been tracked out with such brilliant success, methods more refined than had sufficed for pioneering work must be introduced if all the intricacies of its lanes and by-ways were to be explored. Then the swing of the pendulum rather tended to bring about a disposition to exalt the new means of investigation, and there was just a risk that the sound basis of field-work might come to be undervalued if not neglected; and that Mineralogy and Petrology, instead of being the handmaids of Geology, might be thought to constitute the whole of that science. But the mischief never went far. The mantle which had fallen from the shoulders of the great fathers was not to be lightly cast aside; and, while every new aid was cordially welcomed, the conviction grew stronger and stronger that honest work in the field must for ever be the starting-point of geological inquiry.

How thoroughly this truth has become engrained in the minds of geologists is seen directly we open Prof. Cole's "Aids in Practical Geology." A large part of the book is taken up with minute and precise directions for carrying out the various kinds of microscopical, optical, and chemical examination of minerals and rocks. But on the first page we read—

> "Such aids in determinative geology as are given in the following pages may be applied in any halting-place, or in cities after the return from an expedition; but, in any case, observations made on specimens are of slight importance if uncoupled with knowledge of their true position in the field."

And again—

> "After a study of a number of type specimens, the student is recommended to go out to some well-described district, and to endeavour to recognize the varieties of igneous and sedimentary rocks by careful observation in the field. In this way alone can he appreciate the various modes of weathering, the massive or minuter structures due to jointing, the smooth or rugged outlines that characterize the masses of which his hand-specimens form a part. . . . Nothing short of striking the rock-mass *in situ* with the hammer, and taking in with the eye its position and surroundings, even to the broader features of the landscape, should content the geologist who would follow worthily the founders and masters of the science."

Again and again the author reiterates the lesson—

> "Just as no mountain mass can be described by a stranger from a number of hand-specimens, however beautiful, so no rock can be adequately described from isolated microscopic sections. Again and again the observer will pass from his section to the solid specimen, and from this, in memory at any rate, to the great mass of which it formed a part."

And in dealing with the nomenclature of igneous rocks, the chaotic state of which is so largely due to the ignoring of their field-relations, it is insisted that—

> "The following out of an igneous rock in the field is a most important lesson, and will soon determine what is valuable and what is valueless in any proposed scheme of classification."

That the author, in these and similar passages, is not speaking from hearsay, not merely re-echoing what is now a truism, is shown by the admirable practical directions which he gives in the first chapter for the outfit and procedure of the field-geologist. Here, and indeed throughout the book, the instructions are detailed and precise

The author has not forgotten the time when he was a beginner, his early failures, and the disappointments of his student-days, when, from the neglect of some slight precaution, he failed to obtain the results he had been led to expect; and he has used every means in his power, by minute and specific instruction, to shield those who use his book from similar mishaps. As an instance, take what he says about the effect of acids on minerals. How often has the self-taught man turned wearily to one book after another on mineralogy, in the hope of getting some definite information on this point, and all he arrived at was the curt statement, "Soluble in acids," which each apparently had copied from its predecessor, or all had borrowed from some common source. What acid? Concentrated or dilute? Cold or hot? Quickly, or perhaps only after a fortnight's boiling? All these points he was left to make out for himself as best he could. The happier pupil of Prof. Cole is treated far more liberally, and will not have to weary himself by feeling about in the dark if he attend to the cautions and instructions of the book now before us. The directions for blowpipe-work are equally precise. Only one who has been himself an actual worker would have told the observer to wait "till the first red glow has gone off" before noting the colour of a borax-bead. Of course, anyone would, sooner or later, find this out for himself; but, till he had found it out, he would probably blunder not a little; and anything that economizes time nowadays is not to be despised. There is no need to multiply instances; everyone who uses the book will find that it eminently deserves the epithet of "practical," which the author has assigned to it.

But are there no weak points on which the critic may exercise his function? Attention may perhaps be called to the following:—On p. 6, a graphical method, due to Mr. Dalton, is given for determining the full dip of a bed from the dips on two oblique sections. The writer may perhaps be pardoned for preferring a method of his own, given first in the *Geological Magazine* for 1876, p. 377. But, independently of any personal predilection, it may be said that the diagram in the case of this method is simpler than in that of Mr. Dalton. This makes it easier to recollect, and, besides, the fewer lines there are in a graphical construction the less is the chance of error. In dealing with "streak," it would be well to notice that the true streak of some hard minerals, Iron-glance for instance, is not obtained till they have been rubbed down in an agate mortar.

Doubt is thrown on the value of Turner's test for the detection of boron (p. 41): there is an article by Dr. C. Le Neve Foster in the *Mineralogical Magazine* (vol. i. p. 77) which should be consulted in this connection.

It is hardly worth while criticizing the nomenclature and classification of the crystalline rocks. No two petrographers are in agreement here, and probably the existing schemes of arrangement are all of about equal value. There is fortunately no multiplication of species or introduction of new names. It might be possible to take objection to the description of Quartz-felsite as a compact form of Granite, for the part played by the quartz in the two rocks is totally different, and must be correlated with a difference in their mode of consolidating. Quartz-felsites are specially common as dykes, and there may have been facilities for the escape of water in their case, up the fissures which they fill, that were not present in the case of the more thoroughly buried magma of Granite. It was doubtless the presence of water in the granite-magma which kept the quartz fluid or plastic after the other minerals had crystallized; its escape in the case of Quartz-felsite may have led to the early crystallization of the quartz. In dealing with the foliated rocks, the author touches on the debated point of the "true schists." We are pretty well used to this phrase, and have waited long in the hopes of being told what constitutes a "true schist," but our patience has not yet met with the reward it merits. The author is of opinion that "the alleged distinction between schist-like rocks and schists of pre-Cambrian age requires great delicacy of definition." This is delicately put, and will command the assent of most geologists.

The palæontological section will perhaps be looked upon somewhat derisively by those well versed in biology. But it will serve its end, which is to enable those who cannot pretend to any large amount of biological knowledge to know the commoner fossils when they see them, and determine the genus to which they belong. The method may have a large element of "rule-of-thumb" about it, it may be called empirical, but in a large number of cases it is not practicable to attain to anything better. And it has a certain educational value, for it makes a student use his eyes even if it but slightly disciplines his reason.

That the work deserves its title, that it is full of "aids" and in the highest degree "practical" will be the verdict of all who use it.

Nor will Dr. Hatch's handy volume be any less welcome. Those who wish to have in a compact form the prominent characters of the rock-forming minerals and the igneous rocks, will find all the information needed by a student concisely and lucidly put forth. Some slight acquaintance with crystallography and the optical properties of minerals is assumed. A short section on these subjects would have made the book more self-contained, and need not have increased its size very materially.

The igneous rocks are defined to be "those that have been formed by the consolidation of molten material." There is a spice of danger in the word "molten," for it may lead to the belief that the fluidity of the material was the result of "dry heat." In the case of a Laccolite the view so generally held is taken, that the overlying beds have been bent up by the intrusion of a molten mass. It is, to say the least, quite as likely that earth-movement caused a differential amount of bending in two adjoining beds, and that, as an empty space was thus gradually formed between the two, the molten matter was driven into it.

On the subject of the classification of the igneous rocks we find the following healthy expression of opinion: "The various types are so intimately related, that any attempt at rigid and systematic classification is not likely to meet with any great measure of success." Certainly not till some sounder basis of classification than any yet suggested is hit upon. In the meantime Dr. Hatch's grouping is one that from its clearness and simplicity will be a real boon to the student.

A most useful feature in the book is the list of localities where each rock occurs. The illustrations are very well executed. Though the book has appeared only recently, one teacher at least can already bear testimony, founded on actual experience, as to its value to students.

A. H. GREEN.

BACTERIOLOGY.

Les Virus. Par Dr. S. Arloing. (Paris: Ancienne Librairie, Germer, Baillière, et Cie., 1891.)

THE name of Dr. S. Arloing as the author of a work on bacteriology is a sufficient guarantee that the book is worth reading, nor are we disappointed. "Les Virus" is one of the best volumes on this science yet produced. It is not a mere compilation of other men's work, giving a categorical account of the numerous pathogenic and non-pathogenic bacteria now recognized, but is a thorough scientific investigation into the principles of one of the most important branches of medical science, and might perhaps be better called a manual of "microbiology."

The work is divided into six parts, under the following heads:—

(1) General considerations as to the nature of the bacterial poison.

(2) Form and mode of life of the microbes (biology).

(3) The part taken by the microbes in the propagation and spread of infectious diseases.

(4) Struggle of the host against the poison. Natural extinction and artificial destruction of its effects.

(5) Immunity enjoyed by the body against certain microbes.

(6) Attenuation and reproduction of the bacterial poison.

It will be seen by the above list that this work covers a large field, and one not exactly dealt with by any previous author.

In the first part, which is subdivided into six chapters, Dr. Arloing commences with an historical survey of the science of bacteriology, pointing out the gradual extension of ideas from the time of Rhazes, who, in the ninth century, attributed small-pox to a process of fermentation "comparable to that which takes place in the juice of the grape when made into wine"; touching then on the works of Rayer, Davaine, Chaveau, and others, the author traces the development of the science until present times and the discoveries of Koch and Pasteur. An interesting comparison of the "virulent" parasites with simple parasites, such as *Trichina spiralis*, then follows; and, next, the formulation of two statements which form the basis of the modern science: (1) the active agents of the virulent process are organisms; (2) these organisms are living, and possess specific properties.

The second part of the work deals with the biology of bacteria. The methods of cultivating them are fully described, and, what we do not remember to have seen in any other work on bacteriology, there is a full account of the effect on micro-organisms of nourishment, temperature, light, atmospheric conditions, and electricity. In this part, also, are two most important chapters—namely, the effects on the microbes of the nature of the cultivating medium. This is only just beginning to be properly understood, and its investigation has already been productive of valuable results.

The chapter on the products of the growth of micro-organisms is hardly up to the general excellence of the work. It has not been sufficiently brought up to date, so that the researches of Dr. Hankin, and the more complete investigations of Dr. Sidney Martin in reference to the albuminoses and alkaloids, do not appear in it. The diastases and ptomaines are, however, fully discussed, and much may be learnt from a perusal of this chapter.

The third division of the book is devoted to the *rôle* which the microbes play in the propagation and causation of disease. The chapter on contagion is one of the best in the book, and would alone form a most valuable *brochure*. After a consideration of the general modes in which contagion is carried, a most exhaustive account is given of air, water, soil, food, and artificial inoculation (vaccination) as carriers of disease. As a natural sequence, the modes of entry of the germs into the body are then described, auto-infection being included; and next we have a consideration of what may become of the organisms after their entry, and the changes which take place in the host. The descriptions here given are exceedingly precise, and, although rather condensed, convey all that can be desired.

Passing now to the fourth part, we find four chapters devoted to the strife between the host and the microbes, and the natural extinction and artificial destruction of the poison. In the third chapter the subject of disinfection is noticed, both by heat and antiseptics, special attention being drawn to the necessity of the careful disinfection of sputum, linen, bedding, &c.,—points which cannot be too strongly insisted upon in all hospitals, and not merely in those devoted to fevers or diseases of the chest.

The fifth part deals with the very difficult, and, at present, vague subject of "immunity." Dr. Arloing divides immunity into two classes—"acquired" and "natural." On this subject no one is more qualified to speak than the author of this work, for he has made it almost a special study for years, and it is treated of in his usual masterly way.

The sixth and last part contains some of the more recent researches (especially those of Pasteur) on the attenuation of the virus.

Taking the work as a whole, we cannot speak too highly of it. We heartily congratulate the author on the success of his labours. The book is well illustrated, and we cordially recommend it to all those who wish to study a subject so replete with interest and of such vital importance to mankind.

F. J. W.

OUR BOOK SHELF.

Anleitung zur Bearbeitung meteorologischer Beobachtungen für die Klimatologie. Von Dr. Hugo Meyer. (Berlin: Julius Springer, 1891.)

WERE this little book less severely technical in form, it might be commended to the notice of that large class of observers whose sole aim and object in meteorological registration is to ascertain the characteristics of the local climate and to compare them in detail with those shown by the similar records of other places. It teaches how the results of observation may be tabulated or graphically represented in the forms most approved by climatologists, and discusses with much precision the meaning of different kinds of mean values; though, indeed, it omits all mention of the geometric mean, the application of which in climatology was lately under discussion in the Royal Meteorological Society. But it is, we fear, hardly elementary enough to meet the requirements of beginners and amateurs, especially such as regard a formula of any complexity with something of that distant respect that they accord to holy mysteries; and on the other hand it aims at nothing beyond the formal and statistical presentment of facts, and never deviates into the seductive, if sometimes illusive, field of physical causation. It is what its title proclaims it to be, a guide to the working out of meteorological observations for the purposes of climatology—the climatology, that is to say, of the temperate zone. For those who work in a more extended field, some of the author's methods and dictates may be found to need modification. His schedule of the usual hours of observation makes no mention of those most frequently observed in the tropics, and his uncompromising condemnation of the use of Lambert's formulæ in reducing wind-registers, however justifiable in the case of the variable winds of these latitudes, ignores that of countries where trade-winds or monsoons blow steadily for weeks or months together with but little deviation from the normal quarter, and where the direction undergoes a regular oscillation daily. In working out this daily oscillation at such places, the use of Lambert's formula is not only justified but almost indispensable.

Within the somewhat narrow limits that Dr. Meyer has prescribed to himself, he has executed his task carefully and conscientiously, but in this country, at least, his merits are likely to be appreciated by only a small class; chiefly, indeed, by that estimable few who find in plodding labour its own sufficient reward. The student who is endowed with some share of scientific imagination, who loves to trace the inner workings of Nature, and sees in diagrams and tabulated statistics only means to this end, will find Dr. Meyer's work a somewhat dry study; and when he shall have mastered its contents, should he ever be challenged by Arthur Clough's "Questioning Spirit," and asked,

> "What will avail the knowledge thou hast sought?"

he must answer as he best may from his own mental resources. His author, at least, will not help him to a reply.

Intensity Coils: how made and how used. By "Dyer." Sixteenth Edition. (London: Perken, Son, and Rayment.)

In this book a simple and interesting account is given of galvanic batteries, induced electricity, and the methods of making and using intensity coils, which include numerous experiments that may be described briefly as "popular." In the present edition many other branches of the subject have been touched upon, including electric lighting, electric bells, electric telegraph, electric motors; and a few words are said on the telephone, microphone, and phonograph. Although the book is not presented as a scientific treatise, but simply as a guide containing the necessary instructions for making and using the above-named instruments, yet by its means many may be led to make a more advanced study of the subject, which to-day is of such high importance.

General Physiology. By Camilo Calleja, M.D. (London: Kegan Paul, Trench, Trübner and Co., Limited, 1890.)

The author of this book means by the word "physiology" "discourse of nature"; and his intention is to denote by it "the study of positive science in the abstract sense." The scheme he has set before himself is nothing less than "to comprehend under the fundamental principle of mechanism—conservation of energy—all the laws and theories concerning nature." In order to show the spirit in which he sets about the accomplishment of his task, it may perhaps be enough to say that he regards the planets as "bodies constituted of organic and inorganic matter," and that to him living organic matter seems "the proximate agent of planetary movements, for which non-living bodies are only the cosmic medium." The sun, we learn, is not "a body in combustion," but "principally a great reflecting mass, which, situated in the focus of the orbits of many planets, reflects their infra-luminous emissions, these producing light by their conglomeration." As for "natural light or daylight," it is "a photothermic radiation produced by transference, not only of the radiating motion of the planets, but also of the motion engendered by solar living beings." If anyone is attracted by writing of this kind, he will find plenty of it in Dr. Calleja's amusing volume.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

Co-adaptation.

It sometimes appears to me that the neo-Darwinians must speak a language of their own, because they are so fond of telling me, in a stereotyped phrase, that, "if words have any meaning," such and such words have expressed some meaning which no ordinary grammatical construction can extract. The present is a good case in point. Prof. Meldola says that he finds "a remarkable discrepancy" between my two previous letters on the above subject, and seeks to reveal it by quoting from the first letter, thus:—

"'I do not . . . hold myself responsible for enunciating Mr. Herbert Spencer's argument, which the quotation sets forth. I merely reproduced it from him as an argument which appeared to me valid on the side of "use-inheritance." For not only did Darwin himself invoke the aid of such inheritance in regard to this identical case, ...' &c. If words have any meaning, this implies that Dr. Romanes agrees with Darwin in regarding this case as one in which 'use-inheritance' played a part."

Does it? When a man says that in his opinion a certain argument in favour of a certain conclusion is valid, is this equivalent to his saying that he accepts the conclusion? And when he adds, twice over, that he purposely abstains from expressing any opinion of his own with regard to the conclusion, is this equivalent to his saying the precise opposite?

The state of the case is simply as follows. Prof. Meldola reproduced Mr. Wallace's argument against Mr. Spencer's defence of "use-inheritance." I wrote to show that this particular argument was invalid; but that there was another argument on the same side, which, if adduced, would be valid, *supposing that it could be sustained by facts.* Now, in his reply, Prof. Meldola abandoned the invalid argument, and adopted the one which I had stated. Accordingly I wrote a second time, in order to show that we were then agreed upon this being the only argument which could be logically brought against Mr. Spencer's position. But I again added that I would express no opinion as to whether this argument could be successful in subverting Mr. Spencer's position. In point of fact, with regard to *this* question I have no fully-formed opinion to express. But, unless the neo-Darwinians have eventually become unable to comprehend the attitude of "suspended judgment," one would suppose that they might still appreciate the difference between sifting arguments as good or bad on both sides of a question, and finally deciding with regard to the question itself.

Christ Church, Oxford, May 8. George J. Romanes.

I wrote in good faith when in my last brief communication I expressed the intention of allowing the subject to drop, because I considered that the discussion had arrived at a stage when those who were interested in the matter would be able to form their own opinion as to the value of the arguments adduced on either side of the question. I very much regret to find, however, that Dr. Romanes—whose amount of spare time appears to be most enviably inexhaustible—still finds it necessary to prolong the correspondence. I am compelled, therefore, to enter the field once more, if only for the purpose of presenting my own case in its true light. What Dr. Romanes's position may now be I must confess is becoming distinctly less clear with each of his contributions to the subject, but I am not the first who has lost his way in attempting to thread the mazes of this writer's productions. As far as I am concerned it will suffice to say that the case is not "simply" as he presents it in the foregoing communication. In the review of Mr. Pascoe's book, from which this discussion originated, I did not merely reproduce "Mr. Wallace's argument against Mr. Spencer's defence of 'use-inheritance.'" I accepted that argument as valid, but I extended it by emphasizing the importance of the factor of superimposed useful characters accumulated during successive periods of the phylogeny. I pointed out that large numbers of cases of co-adaptation might be thus accounted for, and I used Mr. Spencer's own illustration by way of example. In summing up his own conclusion, Mr. Wallace says: "The difficulty as to co-adaptation of parts by variation and natural selection appears to me, therefore, to be a wholly imaginary difficulty which has no place whatever in the operations of Nature" ("Darwinism," p. 418). Not only, therefore, has Dr. Romanes misrepresented my view, but he has gone further. The other "argument on the same side" referred to in the above communication is this very denial of co-adaptation as a fact in Nature. This, with most amazing *sangfroid*, is now claimed by my correspondent, who speaks of it as "the one which I had stated"! I must leave it to others to decide what value can be attached to the statements of a writer who adopts the principle of appropriating an argument, and putting it forward in a manner which would lead most readers to consider that he had been the first to elaborate it simply because he has expressed the same idea in abstract symbols instead of in concrete terms.

The next phase in the discussion is the admission by Dr. Romanes that Mr. Wallace's conclusion is correct, *i.e.* that co-adaptation is non-existent: "As it appears to me, from his reply, that Prof. Meldola's views on the subject of 'co-adaptation' are really the same as my own, I write once more in order to point out the identity" (NATURE, vol. xliii. p. 582). Mr. Romanes did more, therefore, than simply point out that we were agreed that this was "the only argument which could be properly brought against Mr. Spencer's position." He said that our views were "really the same," and this after I had accepted Mr. Wallace's conclusion as to the non-existence of co-adaptation. To crown all, he now tells us that he has no fully-formed opinion to express, but that he is in a condition of "suspended judgment"! I must really leave the case as it stands. If "neo-Darwinians" have a language of their own, at any rate it appears to be intelligible among themselves, if only from the circumstance that they have been enabled to stereotype a phrase which conveys their views with respect to the difficulty of following my correspondent's reasoning. I have been no more fortunate than other "neo-Darwinians" in this attempt, but in the endeavour to carry on the discussion of a biological question with a writer who stops short as soon as the subject assumes a truly biological aspect (see NATURE, vol. xliii. p. 582), I have become keenly impressed with the utter sterility of Dr. Romanes's method, which not only fails to advance our knowledge of the origin of species by any substantial contribution of fact, but which degrades the theoretical side of the subject into mere verbiage. If this is "palæo-Darwinism," I am rejoiced to think that I am grouped with those who are outside the pale.

In conclusion, to prevent further misunderstanding, let me add that, in admitting that the chances are "infinity to one" against a number of independent *useful* variations occurring when required in the same individual, I merely quoted the expression as given by Mr. Herbert Spencer and repeated by Dr. Romanes. I do not for a moment suppose that Mr. Spencer used the words in any more than a colloquial sense as indicating that there were "heavy odds" against such a combination, and in this sense only is my admission made. That the phrase has no exact mathematical significance is, I imagine, sufficiently obvious, but I have thought it desirable to make this qualification.

R. MELDOLA.

Physiological Selection and the Different Meanings given to the Term "Infertility."

IN the discussion concerning the segregation of varieties occupying the same region, and the influence of physiological selection in securing this result, it is necessary that we consider the different meanings given to some of the terms by different writers. The general fact on which Dr. Romanes insisted, in his paper on "Physiological Selection," was compatibility in the reproductive system of some, and incompatibility in that of others belonging to the same species. On p. 360 of his paper we read that "racial incompatibility," "however produced," "is the primary condition required for the development of varieties into species." Infertility and sterility are also used by him as equivalents for incompatibility in the reproductive system. Thus, on p. 400 we find the statement that "All natural varieties which have not been otherwise prevented from intercrossing, and which have been allowed to survive long enough to develop any differences worth mentioning, are now found to be protected from intercrossing by the bar of sterility—that is, by a previous change in the reproductive system of the kind which my theory requires."

Dr. Romanes did not attempt to catalogue the different forms of discriminative incompatibility that are included in the incompatibilities of the reproductive systems of different races, but reference was made to three forms: (1) to compatibility in the time of flowering in those of the same race, as contrasted with incompatibility in those of different races, as on pp. 352 and 356; (2) to greater numerical fertility when the male and female elements of the same race unite, than when those of different races unite, as in the note on p. 354; and (3) to numerical infertility through deficient production by hybrids, as on p. 369, and p. 357 in the note, and in the suggested experiments on p. 405, in which the pure and hybrid seed are both to be sown, and the comparative "degrees of fertility" to be noted. To these forms which were mentioned, we may add, as coming under the category of physiological incompatibilities, (4) lack of vigour in hybrids; (5) lack of adaptation in hybrids; (6) lack of escape from competition with kindred in hybrids; and (7) the superior energy and promptness with which the male and female elements unite in pure unions, as contrasted with cross unions. Dr. Romanes probably refers to this principle when he speaks of sterility as "failure to blend" (p. 365).

This last, when associated with the free distribution of the fertilizing elements, ensures the segregation (that is, the discriminative isolation) of two or more varieties occupying the same area and propagating during the same season, and therefore seems to me the most important of the forms of physiological segregation. This segregative principle, which I call potential or prepotential segregation, must, in almost every case, be operative between species and varieties that continue distinct while indiscriminately mingled on the same area and while fertilized by elements freely and indiscriminately distributed during the same season, for no other principle is able to secure free propagation and at the same time to prevent crossing under such conditions. Seasonal segregation is here excluded, and the other forms of physiological segregation when acting under such conditions are of little avail in preventing swamping unless carried to the extreme, and they then involve a waste of from one-half to the whole of the germs of the less numerous variety; for the most favourable case possible is when two varieties occupy the area in equal numbers, and such cases rarely exist, especially in the initial history of species.

Though numerical infertility and tardy potency are readily distinguished, complete impotence and complete numerical sterility are more likely to be confounded; for the complete incapacity of the male and female elements of different varieties for uniting involves failure to produce hybrids, as complete as when the elements unite without producing living offspring or germinating seed. The great difference is that in the case of cross impotence the germ remains unaffected by the alien fertilizing element, and therefore ready to be fertilized by any fertilizing element of its own kind that may reach it; while in the case of simple numerical cross sterility (if there be any such case) the alien elements promptly unite, and therefore leave no opportunity for subsequent fertilization by the coming of the kindred fertilizing elements. Cross impotence, with prepotence of pure unions when associated with the free distribution of the fertilizing elements, produces positive segregation; for, when characterizing varieties occupying the same area, it ensures the propagation of each with its own kind while preventing crossing; but numerical infertility of first crosses produces what I call negative segregation, for, though it is unable to secure segregate breeding, it lessens or obliterates the swamping effects of any crossing that takes place, and is therefore of great importance in the preservation of distinct varieties and species when the positive forms of segregation only partially prevent crossing. The four forms of hybrid inferiority mentioned above are also forms of negative segregation, and, though of the highest importance when co-operating with prepotential segregation or any other principle that partially prevents cross unions, are, it seems to me, incapable of preserving distinct varieties or species, when unassisted by any degree of positive segregation.

We are now prepared to see how the different meanings of infertility have occasioned more or less misunderstanding in the discussion of physiological selection and its effects. With Dr. Romanes, the seven forms of segregation above-mentioned are all forms of infertility between races, and therefore are all causes of physiological selection; while in my nomenclature, all but the first are included under impregnational segregation, and only the second and third are considered forms of cross infertility (or, in other words, of segregate fecundity). Using the term in this restricted sense, I have elsewhere maintained that it is very improbable that cross infertility is, in any case, the only isolative principle securing the continuance of distinct varieties and species indiscriminately commingled on the same area, even when the elements are freely distributed; and as this statement is liable to be taken as equally applicable to physiological selection, I wish to have it clearly understood that, in my usage, the two terms are not equivalent, and what I have said of cross infertility is not in the same sense true of physiological selection.

In Dr. Wallace's criticism of physiological selection, he seems to limit the meaning of infertility between races to numerical infertility of first crosses, and then assumes that this is the only incompatibility that is included under physiological selection. This limitation, if correct, would of course limit the effects that could properly be attributed to this principle.

Before closing I wish to raise the question whether a high degree of selective numerical fertility between races is not always associated with some degree of selective potential fertility. Or, using infertility in the more restricted meaning given in my nomenclature, is not a high degree of segregate fecundity and cross infertility always associated with some degree of segregate prepotence and cross impotence? As we know that these two forms of incompatibility are usually, if not always, associated in the segregation of species, is it not probable that they are similarly associated in the segregation of varieties? Again, as we know that segregate prepotence, when associated with the free distribution of the fertilizing elements, will produce prepotential segregation, effectually preventing crossing, without impairing powers of survival, and as there are many cases in which the continued segregation of varieties occupying the same area is due entirely to this principle, and many other cases in which it is due to weakened forms of this principle associated with other forms of incompatibility in the reproductive system, and still other numerous cases in which partial isolation (produced by a slight diversity of habits, or by the occupation of adjoining districts) would be speedily broken down except for these physiological incompatibilities, are we not fully warranted in the assertion that physiological selection is an essential factor in the evolution of many species?

The importance of this form of segregation having been recognized, the question naturally arises as to what have been the causes through which the incompatibility has ceased to be sporadic, and has become racial. As Dr. Romanes has not entered on the discussion of this point, I have given the more attention to it. I think I have succeeded in showing: (1) that any portion of a species subject to temporary isolation, through occupying a new station or district, is more or less liable to become incompatible with the rest of the species, owing to the cessation of reflex selection, by which the mutual fertility and other compatibilities of an inter-generating stock are kept in force (see NATURE, vol. xlii. pp. 28 and 369); (2) that partially segregative endowments are, through the very laws of propagation, cumulative (see "Divergent Evolution," Linn. Soc. Journ. —Zool., vol. xx. pp. 246–260); (3) that all the transformations that arise in forms thus segregated are inevitably divergent, and not parallel (see "Intensive Segregation," Linn. Soc. Journ.—Zool., vol. xxiii. pp. 312–322). JOHN T. GULICK.

Propulsion of Silk by Spiders.

THE author ("O. P. C.") of the article on "Arachnida" in the "Encyclopædia Britannica," says:—"The emission of silk matter appears to be a voluntary act on the part of the spider; but it is a disputed question among arachnologists whether spiders have the power forcibly to expel it, or whether it is merely drawn from the spinnerets by some external force or other. Mr. Blackwall, author of the 'History of Spiders in Great Britain and Ireland,' is of the latter opinion. Mr. R. H. Meade (Yorkshire) in Report of the British Association, 1858, thinks, that (from microscopic anatomical investigations which he has himself made) there is good evidence of spiders having the power to expel it; for he finds a certain muscular arrangement which would apparently suffice to give this power, and observers have actually seen the lines propelled."

Owing to the doubt herein expressed, may I ask your insertion of a chance observation lately made by me upon a spider, which has convinced me of the truth of the theory that spiders do expel their lines at will, and this, too, as secondary to one still remaining attached to the spinnerets?

She was hanging from the ceiling about 3 feet from a mullioned window, against which I was able to observe her movements most accurately. I was first led to observe her closely, by finding myself attached to her within one minute of my approach. On my breaking this line, she attempted to regain the ceiling; a breath of air from me stopped and brought her down again, when I saw her draw her legs together, pull her head up higher than the spinnerets of her abdomen by means of her ceiling-line, and, *following upon no visible effort of hers whatever*, I was the next moment conscious of the presence of another line stretching out from her spinners to a distance short of 3 feet, and at an angle of about 75° with the first. This line failing to find an attachment floated upwards and lay alongside of the other, and the spider again made for the ceiling. Nine times during the space of one hour, I got her to repeat this attempt to make a horizontal connection. Between two of the intervals of her attempts, I called in two naturalist friends who both witnessed with me, *and at the same instant of time*, the sudden appearance of the new line.

With each successive trial, I was able to substantiate and improve my observation; at first the appearance of the line seemed instantaneous, as to its whole length; next I was able to detect its elongation of itself after about 2 feet of its length was visible; then I could see it leaving the spinnerets; and finally, during the last moment of its travel, I could perceive very distinctly that it drew the spider slightly forward.

From these premises I can but infer that the viscid matter contained by the silk-glands, which, at the ordinary slow rate of emission, turns to gossamer immediately upon its exposure to the air, when expelled as now, violently, remains viscid sufficiently long to reach a certain distance.

These secondary threads, carried towards the ceiling by the spider, were never brought down again when she fell to the length of the main line, but were each time left, disconnected from her, at the spot from whence she fell when I blew her. Their loose end invariably floating upwards until alongside of the spider's main line, was, I think, noteworthy.

In conclusion, I would say that *sight* seemed to play no part in her choice of a direction for the connecting line; though I was close to her all the time, and indeed the only object apparently which was close enough, she only hit me the first time, when perhaps she had *heard* my approach; this may strengthen the remarks made by Mr. C. V. Boys in your number for November 13, 1890, where he says: ". . . . sight, as we understand the term, in spite of their numerous eyes, seems to be absent." S. J.

The Crowing of the Jungle Cock.

I THINK there can be little doubt that Mr. H. O. Forbes has fallen into the same mistake as I had, in regard to Mr. Bartlett's statement that "none of the known wild species are ever heard to utter the fine loud crow of our domestic cock."

At first I took this to mean that the jungle cock did not crow *at all*, and was collecting notes from sporting men here, to supplement my own 26 years' experience, when yours of February 5 arrived, and by it I see that Mr. Bartlett implies that the crow is not so full, loud, and long, as that of our barn-door cock.

Mr. Forbes exactly gives the difference, as thinner, more wiry, and high pitched; it is also shorter, at least in the wild *G. ferrugina.* These I have often heard crowing, and shot in the extreme east of Asam, where for a very large area, on the Upper Diking River, and across Patkai, there are no inhabitants.

This same *G. ferrugina* is, however, to be found wild all over Asam, and the countries around; eggs found in the jungles are often hatched under domestic fowls, and hence these are frequently crossed, and the crow of the cock varies much in consequence.

But the difference between the wild *G. ferrugina* and our "barn-door" cock, in this particular, is so well marked that it could *invariably* be detected.

I may perhaps mention a curious sight I saw last year, within 100 yards of my bungalow, in the evening. A cloud of white ants were rising on the air, in the main road, and a jackal and jungle cock were busy eating the "neuters" swarming all over the ground; presently another jackal joined and the cock was between them: all were so busy feeding that they took no notice of each other, the jackals often lying on their bellies, while the cock moved about between them, at 2 or 3 yards only. By this time 15 or 20 people were looking on and laughing. Suddenly a third, younger jackal, joined the group, and after eating the ants a short time, and walking about like the others, dropped into the ditch and *stalked* the cock, crouching close to him. The latter at once flew, and made a bee line for the forest 400 yards off. The total area of the ants was about 20 feet by 8 only.

Antipathy [?] of Birds for Colour.

WITH regard to the destruction of the yellow crocus by the sparrow, mentioned by your correspondent "M. H. M." in NATURE, vol. xliii. p. 558, this bird appears to have a predilection for yellow. In an article on "Birds' Nests and Nest-building," in the *Animal World*, present number, an instance is given of sparrows using the flowers of the laburnum for their nest. Only lately I have been watching them picking out the yellow centres of the daisy, but in this case *it was for food*, and I am inclined to believe that some portion of the crocus is also eaten. At this time of the year they are well known to be partial to buds and flowers of different kinds—for instance, the blossoms of the gooseberry bushes.

Doubtless, the bright yellow colour attracts the attention of this now much censured bird, so omnivorous in his tastes and such a general scavenger, and therefore not wholly to be condemned.

The Destruction of Fish by Frost.

REFERRING to Prof. Bonney's letter in NATURE, vol. xliii. p. 295, regarding the destruction of fish by frost, and in which he asks for information from more northern latitudes, I may say that during the winter of 1885–86, at Cape Prince of Wales, Hudson's Strait, when the thickness of ice in a small lake was being measured, live fish were often seen; and upon the last occasion, when the ice measured six feet and half an inch, several were thrown up with the water that, upon our cutting through, immediately overflowed. These fish were about an inch and a half in length and were extremely lively. I may add that during the summer both feeder and outlet of the lake averaged about eight inches in depth and the lake nine feet in its deepest part. The former ceased to flow on November 8, when, too, ice, fourteen inches in thickness, covered the lake.

The Flying to Pieces of a Whirling Ring.

WITH reference to the recent discussion in your columns on the whirling of steel bands, the following results will be of interest.

A weldless steel flask, with spherical body 12 inches in diameter and ⅜ inch thick, constructed for use in a centrifugal milk separator, to revolve about its axis of symmetry at a normal speed of 7000 revolutions per minute, was whirled at a gradually increasing speed, with a view to ascertaining the "bursting" velocity.

At 16,000 revolutions per minute the body of the flask had bulged 2 inches in diameter: this is equivalent to an extension of 17 per cent. of the circumference; the peripheral speed being 840 feet per second, and the tension 31·5 tons per square inch.

The experiment was not continued, as it was considered sufficiently satisfactory, and the bulged flask is kept as a curiosity.

HERTZ'S EXPERIMENTS.[1]

III.

IN the last article the principles upon which a rapidly vibrating electric oscillator should be constructed were considered, and how the sudden break-down of the air gap enabled these rapid vibrations to be started. It is probable that this break-down occurs in a time smaller than the thousand millionth of a second. How very rapid interatomic motions must be!

Consider now the principles on which an apparatus is to be constructed to receive the vibrations produced by this oscillator. We may observe in the first place that as we are dealing with a succession of impulses at equal intervals of time we can utilize resonance to accumulate the effect of a single impulse. Resonance is used in an immense variety of circumstances to accumulate the effect of a series of impulses, and is avoided in another immense variety of circumstances to prevent accumulating the effect of a series of impulses. We see, we hear, we photograph by using it; we use it to make musical sounds, to keep clocks and watches going, to work telegraphs. By avoiding it carriages drive safely over rough roads, ships navigate the seas, the tides do not now overwhelm the land, the earth and planets preserve their courses round the sun, and the solar system is saved from destruction. Resonance may be thus described:—If a system is able to vibrate by itself in any way, and if we give it a series of impulses, each tending to increase the vibration, the effect will be cumulative, and the vibration will increase. To do this the impulses must be well timed, at intervals the same as the period of vibration of the system itself. Otherwise some of the impulses will tend to stop the vibration, and only some to increase it, and on the whole the effect will be small. In order to use resonance in the construction of the detector of waves of electric force, we must make our detector so as to be capable of an electric vibration of the same period as the generator of the waves. If we do this we may expect the currents produced in it to be increased by each wave, and thus the electrification at its ends to increase, and so increase the chance of our being able to produce a visible spark. Two ways of using a detector have been mentioned. One is to observe the heating of a conductor by the current in it, and the other to observe a spark due to the electrification at the end of the conductor. The latter is the most sensitive and has been most frequently employed, and is the method first employed by Hertz. Two forms of detector may be used for observing sparks. One form consists of a single conductor bent into a circle with its two extremities very close together. An electric charge can oscillate from one end of this to the other round the circle and back again. If the circle be the proper size, about 70 cm. in diameter for the large sized oscillator and about 8 cm. in diameter for the smaller sized one described in the last article, the period of oscillation of this charge will be the same as that of the charge on the generator of the waves, and its oscillation will be increased by resonance until, if the ends of the circular wire be close enough together, the opposite electrification of the ends will become great enough to cause a spark across the gap. The other form of detector depends on using two conductors, each of which has the same period of electric oscillation as the oscillations we wish to detect. These are placed in such a position that an end of one is near that end of the other which will at any time be oppositely electrified. For example, if the electric force in our waves be in vertical lines, then if we place two elongated conductors, one vertically above the other and separated by a very small air space, the electric force alternating up and down will cause currents to run up and down the conductors simultaneously, and the upper ends of both will be similarly electrified at any instant, while the lower end of the upper one will always be oppositely electrified to the upper end of the lower conductor, and if these two points, or two short wires connected with them, be close enough together, a spark will pass from one to the other whenever the electric force sets up these electric oscillations in the conductor. Thus this apparatus is a detector of the electric force. Whenever there is a spark we may be sure that there is electric force, and whenever we cannot get a spark we may be sure that there is either no electric force or anyway too little to produce sparks. The apparatus will be more sensitive for electric forces that oscillate at the same rate as the natural vibration of the electric charge on the conductor, because the effect of each impulse will then add to that of the last; resonance will help to make the electrifications great, and so there will be a better chance of our being able to produce a spark. We may weaken the strength of this air gap by reducing the pressure of the air in it. To do this the ends of the conductors, or wires connected with them, must lead into an exhausted air vessel, such as a Geissler's tube. There is no doubt that much longer sparks may thus be produced, but they are so dim and diffused that when dealing with very minute quantities of electricity those sparks in a vacuum are not more easily seen than the smaller and intenser sparks in air at atmospheric pressure. The additional complication and difficulty of manipulation from having the terminals in a vacuum are not compensated for by any advantages. This whole detecting apparatus works on somewhat the same principle as a resonator of definite size connected with one's ear when used to detect a feeble note of the same pitch as the resonator. Such a resonator might very well be used to find out where this note existed and where it did not. It would detect where there were compressions and rarefactions of the air producing currents of air into and out of your ear. In the same way the conductor sparking tells where there are alternating electric forces making currents alternately up and down the conductor, and ultimately electrifying the end enough to make it spark. In the sound resonator there is nothing exactly like this last phenomenon. We have much more delicate ways of detecting the currents of air than by making them break anything. If anybody would allow the electric currents from a Hertzian detector to be led directly into the retina of his eye, it would probably be a very delicate way of observing, though even in this direct application of the current to an organ of sense it is possible that these very rapidly alternating currents might fail to produce any sensible effect, for they are not rapid enough to produce the photochemical effects by which we see.

---

[1] Continued from p. 14.

To recapitulate the arrangements proposed in order to detect whether electric force is propagated with a finite velocity, and if possible to measure it if finite. It is proposed to create electric oscillations of very great rapidity, oscillating some four or five hundred million times per second, and it is expected thereby to produce waves of electric force whose length will be less than a metre if they are propagated with the velocity of light. It is proposed to do this by causing an electric charge to oscillate backwards and forwards between two conductors, and across an air gap between them. This oscillating charge is to be started by charging the conductors, one positively and the other negatively, until they discharge by a spark across this air gap. By making the conductors small, and the distance the charge has to go from one to the other small, the rate of oscillation of the charge can be made as great as we require. If waves are produced by this arrangement, we can reflect them at the surface of a large conducting sheet, and then loops and nodes will be produced where the incident and reflected waves co-exist. The loops will be places where the alternating electric forces are great, while at the nodes there will be no electric forces at all. In order to detect where there are these alternating electric forces and where there are none, it is proposed to use either a single wire bent nearly into a circle, with a very minute air gap between its ends, or else two conductors placed end to end, with a minute air gap between their ends. In either case, if the natural period of vibration of a charge on the single conductor, or on each of the conductors in the second arrangement, is the same as the rate of alternation of the electric force we wish to detect, there may be sufficient electrification of the neighbouring ends to cause a spark across the minute air gap. We are thus in possession of a complete apparatus for determining whether electric waves are produced, and what their wave-length is.

The experiment is conducted as follows:—

The two conductors which are to generate the waves are placed, say, one above the other, so that the electric charge will run up and down in a vertical line across the spark gap between them. They might be placed horizontally or in any other line, but for definiteness of description it is well to suppose some definite position. We may call them A and B. They are terminated in polished knobs, between which the spark passes. A and B are connected with the terminals of a Ruhmkorff coil, or a Wimshurst or other apparatus by which a succession of sparks may be conveniently made to pass from A to B. Before the spark passes, A and B are being electrified, and when the spark occurs the electricity on A rushes over to B, and part of it charges B, while the electricity on B rushes across the spark, and partly charges A, this taking place alternately up and down. Each time there is less electricity, for some is neutralized during each oscillation by the opposite charge; for energy is being spent, some in overcoming the resistance of the spark gap, *i.e.* in producing the heat developed there, and some in producing electric waves in the surrounding medium. Thus the electric energy of the two oppositely charged bodies A and B is gradually dissipated, and one way of describing this is to say that the two opposite electric charges combine and neutralize one another. This whole language of talking of electric charges on bodies, and electric currents from one to the other, of electric charges neutralizing one another, and so forth, is not in accordance with the most recent developments of electro-magnetic theory. At the same time, those for whom these articles are written are familiar with this language, and with the view of the subject that it is framed to suit, while they are unfamiliar with ether electrically and magnetically strained and thereby the seat of electric and magnetic energy, and consequently it would have added very much to their difficulty in grasping the details of a complicated question if it had been described in unfamiliar terms, and from an unfamiliar point of view.

The electric force in the neighbourhood of the vertical generator will lie in vertical planes through it, and as A and B are alternately positive and negative, the electric force will alternately be from above downwards, and from below upwards. If, then, this force is propagated outwards in a series of waves, we may expect that all round our generator waves of electric force will be diverging; waves in which the force will be alternately down and up. The state of affairs might be roughly illustrated by elastic strings stretched out in every direction from our generator. If their ends at the generator be moved alternately down and up, waves will be propagated along the strings, waves of alternate motion down and up.

In order to reflect these waves, we require a metallic sheet of considerable area some two or three wave-lengths away from the generator; so far away in order that we may have room for our detector to find the loops and nodes formed every half wave-length where the outgoing waves meet those reflected from the screen. Not too far away, or our waves will be too feeble even at the loops to affect our detector. The waves are thrown off all round, but are most intense in the horizontal plane through the spark, so that our detector had better be placed as near to this plane as possible. The detector may be either a very nearly closed circle of wire, or two conductors, each somewhat longer and thinner than the combined lengths of the generating conductors, and placed vertically over one another, and separated by a minute air gap. As the theory of this latter form of detector is simpler than that of the circle, it will simplify matters to consider it alone. The two conductors should each have a period of electrical oscillation up and down it, the same as that of the charges on the generator. The generator consists of two conductors certainly, but then during the time the spark lasts they are virtually one conductor, being connected by the spark across which the electric charges are rushing alternately up and down. Hence the period of oscillation of the charges on the generator corresponds to that on a single conductor of the same size as its two parts combined. Various experiments have been made as to the best form for these conductors that form the detector. They might be made identical with the generator, only that the spark gap in the generator should be represented by a connecting wire. They may be longer and thinner. If longer, they should be thinner, or they will not have the same period of vibration. On the whole, the best results have been got with conductors somewhat longer and thinner than the generator. It is not generally convenient that the spark between the two conductors that form the detector should take place directly from one to the other. It is not easy to make arrangements by which distance apart of these conductors can be regulated sufficiently accurately. The most convenient way is to connect the lower end of the upper conductor and the upper end of the lower one each with a short thin wire leading, one to a fixed small knob, and the other to a very fine screw impinging on the knob. The screw may then be used to adjust the spark gap between it and the small knob with great accuracy. This spark gap must be very small indeed, if delicate work be desired. A thousandth of a centimetre would be a fair-sized spark gap. The minute sparks that are formed in these gaps when doing delicate work are too faint to be seen, except in a darkened room. Having placed the detector in position between the generator and the screen, the difficult part of the observation begins. It is heartrending work at first. A bright spark now and then arouses hope, and long periods of darkness crush it again. The knobs of the generator require repolishing; the spark gap of the detector gets closed up; dust destroys all working; and not without much patience can the art be attained of making sure of getting sparks whenever the conditions are favourable, though it is easy enough not to get sparks when the conditions are unfavourable. Before making any measurements, all this practice must be gone through. It is hard enough with the success of others before us to encourage us, with their advice to lead us, with a clear knowledge of what is to be expected to guide us. How much credit, then, is due to Hertz, who groped his way to these wonderful experiments from step to step, without the success of others to encourage him, without the advice of others to lead him, without any certainty as to what was to be expected to guide him. Patiently, carefully, through many by-paths, with constant watchfulness, and checking every advance by repeated and varied experiments, Hertz worked up to the grand simplicity of the fundamental experiment in electricity that is engaging our attention.

Having gained command over the apparatus, we may look about for places where sparks occur easily, and for others where they cannot be produced. Two or three places may be found where no sparks can be observed. These places will be found to be nearly equidistant. They are the nodes we are in search of. The distance between any pair is half the distance an electric wave is propagated during the period of an oscillation. Their presence proves that the electric force is not propagated instantaneously, but takes time to get from place to place. If the electric force were propagated instantaneously, there might be *one* place where the action of the currents induced in our reflecting sheet neutralized the direct action of our generator; but there could not be a series of two or more such places between the generator and the reflecting sheet. That there are more than one proves that electric force is propagated from place to place, and does not occur simultaneously everywhere. It sets the crowning stone on Maxwell's theory that electric force is due to a medium. Without a medium there can be no propagation from place to place in time. It only remains to confirm by calculation that the rate of propagation is the same as that of light. This is a complicated matter. It involves the question of how fast should, on any theory, the charge oscillate up and down a conductor. The problem has only been accurately solved in a few special cases, such as that of a sphere by itself. The conductors that have been employed are not this shape, are not by themselves, and so only rough approximations are possible as to the rate at which these oscillations occur. Knowing the wave-length will not determine the velocity of propagation unless we know the period of vibration; and consequently this direct measure of the velocity has only been roughly made; but it agrees as accurately as could be expected with Maxwell's theory that it must be the same as the velocity of light if electrical phenomena are due to the same medium as light. The conviction that more accurate determinations will confirm this agreement is founded upon safe ground. It was pointed out that the ether that transmits light and is set in vibration by the molecules of matter can hardly avoid moving them itself. This ether can hardly help having other properties than merely transmitting a comparatively small range of vibrations. It can hardly help producing other phenomena. When it has been shown that, if there is a medium concerned in conveying electric and magnetic actions, it must possess properties which would enable it to transmit waves like light; and when it has been shown that there *is* a medium concerned in conveying electric and magnetic actions, and that the rate at which they are conveyed is approximately the same as the rate at which light is propagated; the conclusion is almost unavoidable that we are dealing with the same medium in both cases, and that future experiments, capable of accurate calculation and observation, will confirm the conclusion that electric force is propagated through, and by means of, the luminiferous ether with the velocity of light. We really know very little about the nature of a wave of light. We know a great deal more about electric and magnetic forces, and much may be learnt as to the nature of a wave of light by studying it under the form of a wave of electric force. The waves produced by the Hertzian generator may be a metre long or more. The difficulty is to get them short enough. We know a good deal about how they are produced, and from this, and also by means of suitable detectors, we can study a great deal about their structure. They are truly very long waves of light. Atoms are Hertzian generators whose period of vibration is hundreds of millions of millions per second. A Hertzian generator may vibrate rapidly, but it is miserably slow compared with atoms. And yet the wonder is that atoms vibrate so slowly. If a Hertzian generator were, say, 10^{-7} cm. long, about the size of a good big atom, its period of vibration would be some hundreds of times too rapid to produce ordinary light. Atoms are probably complicated Hertzian generators. By making a complicated shape, as, for example, a Leyden jar, a small object may have a slow period of vibration. All that is required is that the capacity and self-induction may be large in comparison with the size of the conductor. We saw that these rapidly vibrating generators have but little energy in them: they rapidly give out their energy to the ether near them. This is also the case with atoms. These, when free to radiate, give up their energy with wonderful rapidity. How short a time a flash of lightning lasts! It is hardly there but it is gone: the heated air molecules have so suddenly radiated off their energy. The reason why atoms in the air, for instance, do not radiate away their energy like this is because all their neighbours are sending them waves. Each molecule is a generator, but it is a detector as well. It is kept vibrating by its neighbours: it occupies a part of the ether that is in continual vibration, and so the atom itself vibrates. As each atom can radiate so rapidly, it must be a good detector: its own vibrations must be very much controlled by the neighbourhood it finds itself in; and as the waves of light are very long compared with the distances apart of molecules, those in any neighbourhood are probably, independently of their motions to and fro, each vibrating in the same way. It is interesting to calculate how much of the energy in the air is in the form of vibrations of the ether between the molecules of air. A rough calculation shows that in air at the ordinary density and temperature only a minute fraction of the total energy in a cubic centimetre is in the ether; but when we deal with high temperatures, such as exist in lightning-flashes and near the sun, and with very small densities, there may be more energy in the ether than in the matter within each cubic centimetre. All this shows how wide-reaching are the results of Hertz's experiments. They teach us the nature of waves of light. We can learn much by considering how the waves are generated. Let us consider what goes on near the generator, consisting of two conductors, A and B, sparking into one another. Before each spark, and while A and B are being comparatively slowly what is called charged with electricity, the ether around and between them is being strained. The lines of strain are the familiar tubes of electric force. If A be positive, these tubes diverge from all points of A, and most from the knob between it and B, and converge on B. Where they are narrow, the ether is much strained; where wide, the ether is but little strained. Each tube must be looked upon as a tube of unit strain. The nature of the strain of the ether is not known; it is, most probably, some increased motion in a perfect liquid. We must not be surprised at the nature of the strain being unknown. We do not know the nature of the change in a piece of india-rubber when it is strained, nor indeed in any solid, and though the ether is much simpler in structure than india-rubber, it can hardly be wondered at that we have not yet discovered its structure, for it is only within the present century that the existence of the ether was demonstrated, while men have known solids and studied their properties and structure for thousands of years. Any way, there is no doubt that the ether is strained in these tubes of force when A and B are oppositely charged, and that the energy per cubic centimetre of unstrained ether is less than that of strained ether, and that the work done in what is called charging A and B is really done in straining the ether all round them. When the air gap breaks down, and an electric spark takes its place, there is quite a new series of phenomena produced. Suddenly, the strained ether relieves itself, and, in doing so, sets up new motions in itself. The strained state was probably a peculiar state of motion, and in changing back to ordinary ether a new and quite distinct state of motion is set up. This new state of motion all round the conductors is most intense near the spark, and is usually described as an electric current in the conductors and across the spark, or as a rushing of the electric charge from one conductor to the other. The electric current is accompanied by magnetic force in circles round it, and the tubes of magnetic force define the nature of the new movement in the ether as far as we know it. Hitherto, for the sake of simplicity, the existence of this magnetic force has been unnoticed. It is due to a peculiar motion in the ether all round what are called electric currents. The current in fact consists of little else than a line, all round which this movement is going on; like the movement surrounding an electrified body, but also unlike it. Whenever electric forces are changing, or electrified bodies moving, or electric currents running, there this other peculiar motion exists. We have every reason for thinking that this, which may be called the magnetic strain in the ether, as the movement all round electrified bodies was called the electric strain—that this magnetic strain only exists in these three cases: (1) when the electric strain is changing; (2) when electrified bodies are moving; and (3) when electric currents are running. These three may be all cases of one action: certainly the magnetic strain that accompanies each is the same, and it seems most likely that the electric change is only another aspect of the magnetic strain. There are analogies to this in the motion of matter that partly help and partly annoy, because they partly agree and partly will not agree with the etherial phenomena. Take the case described in a former article of a chain transmitting waves. Attention was drawn to the displacement of a link and to its rotation. Now for the analogy: to seem at all satisfactory the first thing that would strike one would be to pay attention to two *motions*, to the velocity of displacement of the link and to its rotation. This would lead to interminable difficulties in carrying out the analogy. We cannot liken electric strain to a velocity in this direct and simple way, because, what are we to do with a change in the strain which produces the same effects as a continuous current? A change in the strain is all very well, it would be like a change in the velocity, but what about a continuous change in the velocity: we can hardly suppose a velocity continually increasing for ever: we are evidently landed in immediate difficulties. It is better therefore to be content to liken the electric strain to a displacement of the chain link. It seems most likely that it really is a peculiar motion in the ether, but we must be content for the present with the analogy. If we want to drive it further, we must suppose stress in the chain that draws the link back to be due to a motion in the chain or of things fastened to it, and then the changed motions produced by a displacement of the chain might be analogous to the peculiar motions accompanying electric strain. It would lead us too far to work out this analogy. Returning to the simpler case of the displacement of the link representing electric strain, and the velocity of its rotation representing magnetic strain, see how the actions near a Hertzian generator may be likened to what takes place when a wave is being sent along a chain. While the conductors are being slowly charged we must suppose electric strain to be produced in all the surrounding space. This is a comparatively slow action, and as the rate of propagation is very rapid, the electric strain will rise practically simultaneously in the whole neighbourhood, and that it does so is a most important fact to be taken account of in all our deductions from these experiments. This slow charging must be represented by a slow raising of one end of the chain, which raises the rest of it to a great distance apparently simultaneously if the raising be done slowly. Suddenly the air gap breaks. This might be represented by lifting the chain with a weak thread, and by having the end of the chain fastened to a pretty strong spring. When the thread broke the spring would pull the chain back quickly, would pass its position of equilibrium, and thus commence a series of rapid vibrations on each side of this position; the vibrations would gradually die away owing to the energy of the spring being gradually spent, partly on friction in itself, and partly in sending waves along the chain. In actually performing the experiment, an india-rubber tube or limp thin rope is better than a chain when hung horizontally, as the chain is so heavy; when it can be hung vertically, a chain does very well. In the description it simplifies matters to describe a chain, because it is easier to talk of a link than of a bit of the rope: a link has an individuality that identifies it, while a bit of the rope is so indefinite that it is not so easy to keep in mind any particular bit. Consider now what these waves are, what sort of motion originates them. When the spring first starts, the near parts of the chain move first. What happens to any link? One end of it moves down before the other. What sort of motion, then, has the link? It must be rotating. Thus it is that change in the displacement is generally accompanied by rotation of the links. Thus it is that change in electric strain is accompanied by magnetic strain. The analogy goes farther than this. Each wave thrown off may be described as a wave of displaced or as a wave of rotating links, and the most displaced are at any time the most rapidly rotating links. Just in the same way, what have hitherto been called waves of electric force may also be looked upon as waves of magnetic force. Because there are two aspects in which the motion of the chain may be viewed does not diminish from the essential unity of character of the wave-motion in its waves; and similarly the fact that these Hertzian waves have an electric and a magnetic aspect does not diminish from the essential unity of character of the wave-motion in them. At the same time the two elements, the displacement of a link and the rotation of a link, are quite distinct things; either might exist without the other; it is only in wave propagation that they essentially co-exist. In the same way electric strain and magnetic strain are quite different things; though in wave-motion, and indeed whenever energy is transmitted from one place to another by means of the ether, they essentially co-exist.

FIVE YEARS' PULSE CURVES.

OVER five years ago it occurred to me that there would be considerable interest in keeping a systematic record for some time of the rate of pulsation, *i.e.* of the number of beats (per minute) of the pulse. I therefore commenced the practice by taking, every night, an observation of my own pulse; these observations, originally undertaken solely for my own personal interest, have been continued without intermission up to the present time; and, on throwing the results into a graphic form, I found so close a symmetry and concord between the curves for these five years, that I thought it might be interesting to readers of NATURE to have these results put before them.

First, then, as to the method adopted in these observations. I count the pulse beats for one minute[1] every night[2] before retiring to bed, and invariably while in a standing posture. From the records thus obtained the average for each month is deduced in the usual way, viz. by adding together all the numbers for the month, and dividing by the number of days on which observations were taken. With regard to this important consideration—*i.e.* of the number of observations, since an insufficiency thereof would, of course, greatly vitiate the value of my curves—I may state that during the first four years I omitted to take an observation on only seventeen nights altogether. During the fifth year, I find twenty-one observations missed. Nevertheless, the *net* data from which the curves are deduced are not quite so abundant as this statement would imply; for, in calculating the monthly average, I have invariably struck out altogether *all readings above* 79. My reason for this procedure was simply that I wished to obtain a curve showing the normal pulsations; now, anything much above 75 is abnormally high (especially in my own individual instance, for it will be noticed that my pulse is below the usual average of 70), and I can nearly always assign a distinct cause, such as the feverishness caused by a cold, or excitement, or recent exercise; it therefore appeared to me fairest to knock out altogether the results of such disturbing causes, and since for this purpose an arbitrary line must be drawn somewhere, I decided to draw it at 79. On the other hand, however, I have retained all the other readings, no matter how low they might be, although the "fifties" are very common, and occasionally even the "forties" have been touched. It might, perhaps, be thought that these very low readings should be neglected equally with the very high, but such a course appeared to me altogether illegimate, both because such low readings seemed, judging from their occurrence, to be, so to speak, *normally* caused, and unassignable to any distinct extraordinary cause known to myself, and also because I should hardly have known where to draw a minimum line. However, I now regret that the readings below 50, at any rate, were not rejected; but such readings are so extremely rare that they cannot have much influenced the curves. In order that the reader may judge for himself on what data these curves are founded, I have appended a table showing the *net* number of readings from which each monthly average was drawn, and have also stated (in brackets) the number of readings below 60 included in each month.

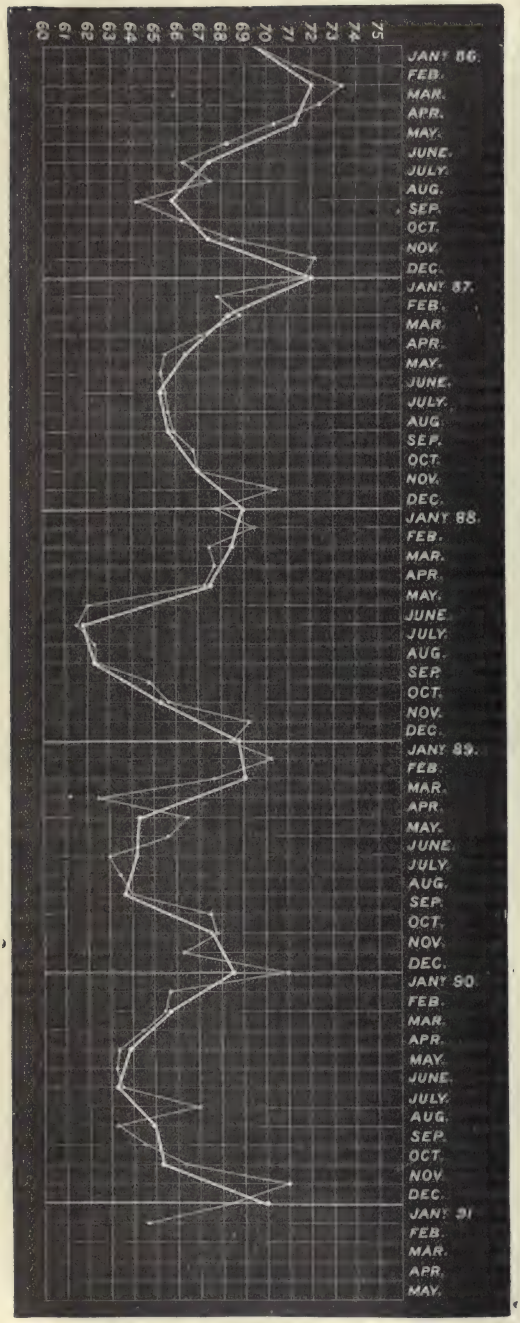
Turning now to the curves themselves, this monthly average is shown by the *thin* line. It is necessary to explain that these curves were drawn by marking the monthly average by a dot on the *extreme right* of each space representing a month. I was undecided for some time whether to adopt this plan or to mark this dot in the *middle* of each monthly space; but after trying both plans I concluded that now adopted to be the simpler. The actual curves were, of course, obtained by connecting all these dots by straight lines.

On examining this monthly curve, it is at once obvious that there is a strong similarity between the five years; clearly every year the curve falls through the spring, until about midsummer, and then rises wonderfully steadily and regularly in every case (except in 1889) through the autumn to November or December. On the whole, two maxima seem to be indicated—namely, one in November, followed by a fall, and then by a rise to another maximum in February or January. But it will be noticed that in the winter 1889-90 there is the unusual phenomenon of a fall through November, and then the two maxima are replaced by an intermediate maximum reached in December. So that here, in spite of the broad concord and regularity, there was rather too much local irregularity to be altogether satisfactory. In the lower portions of the curves, again, there is even more irregularity. Those of 1887 and 1888 (but emphatically the former) are indeed remarkably free from aberration; but in 1886 there is an extraordinarily abrupt and irregular rise through July, followed by a compensating fall through August. In 1890 there is an almost identical irregularity in the same two months; while in 1889 we have a remarkable irregularity in the spring. Now these irregularities puzzled me a good deal; still, in each case

---

[1] Thus avoiding the considerable error that is introduced by counting for, say, fifteen seconds only, and multiplying.

[2] The time has varied from 23.0 o'clock to 1 o'clock.



(except that of the winter irregularity, 1889–90), I could assign a fairly plausible explanation. For instance, during the summer of 1886 I was under medical treatment: in July of 1890 I was touring among the Swiss mountains: while at the end of February 1887 I had removed from a low-lying northern suburb, to a rather higher southern one; this change might with some plausibility be considered as the possible disturbing cause in the 1889 spring curve.

Nevertheless, looking at the results as a whole, I was not satisfied with the curves: it appeared to me as by no means improbable that the monthly average was calculated on a rather too short period, thus allowing temporary disturbing causes to manifest themselves unduly. I therefore determined to try the effect of calculating the averages on a *two-monthly* period, throwing into one total January and February, March and April, May and June, July and August, September and October, November and December respectively. On drawing the curves corresponding to these averages (*thick*-lined curve), I was delighted to find order and symmetry completely regnant: all the aberrations have of course disappeared, and order is supreme. This two-monthly curve clearly shows a single maximum in winter, followed by a fall to the minimum at midsummer, and then by a rise to the winter maximum.

It is evident that the curves for all five years are very closely similar, though by no means identical[1] in nature; but I am especially anxious to point out the extraordinary symmetry displayed by the *curves on either side of a maximum or minimum* point. For instance, the curves for the following periods,

1886 July–October,
,, April–December,
,, November–February 1887,
1888 November–May 1889,
1889 The whole year,

are wonderfully symmetrical, in some cases even being almost geometrically exact.

What, however, may be the exact interpretation of these curves I must leave it to those better acquainted than myself with physiology to decide; but it is worth noting that these curves are exactly contrary to the statement in Michael Foster's text-book, that the pulse *is said* to rise in summer.[2]

The following is the table above referred to as showing the *net* data for each month, and also (in brackets) the number of readings below 60 included in each case:—

1886.		1888.	
January	28	January	25 (1)
February	19	February	23 (1)
March	21	March	24 (3)
April	25	April	30 (4)
May	30 (1)	May	30 (11)
June	29	June	30 (11)
July	30 (1)	July	31 (10)
August	28 (8)	August	28 (9)
September	29 (2)	September	28 (5)
October	29 (1)	October	31 (5)
November	25	November	26 (2)
December	23	December	28 (3)
1887.		1889.	
January	28 (2)	January	25
February	26 (1)	February	23 (2)
March	30 (3)	March	31 (9)
April	27 (4)	April	28 (8)
May	27 (3)	May	28 (3)
June	25 (5)	June	29 (10)
July	31 (3)	July	28 (4)
August	30 (6)	August	28 (7)
September	28 (2)	September	27 (4)
October	30 (2)	October	30 (2)
November	23	November	26 (4)
December	25 (2)	December	25 (1)

---

[1] Seeing how very many causes must co-operate in producing the one resultant—of pulsation-rate—it would be very strange if the curves for different years *were* identical.

[2] I quote from the third edition.

1890.

January	27 (5))	July	24 (2)
February	24 (5)	August	30 (8)
March	28 (4)	September	29 (7)
April	28 (7)	October	24 (5)
May	27 (7)	November	22 (1)
June	26 (8)	December	30

If these numbers be compared with the curves, it will be found that in a rough way they agree with them; the diminishing number of these low readings every autumn, no less than their increase towards the summer, being obviously correlated with the rise and fall of the curves.

F. H. Perry Coste.

THE SCIENCE MUSEUM AND GALLERY OF BRITISH ART AT SOUTH KENSINGTON.

VIGOROUS protests continue to be made against the appropriation, for the new Gallery of British Art, of the site which ought to be used, as originally intended, for the Science Museum. Several letters on the subject by men of high authority have been printed in the *Times*; and on Tuesday a deputation, which could not but command attention and respect, waited upon Lord Cranbrook and Mr. Goschen to represent to them the opinions held by all who are in a position to form a trustworthy judgment on the question. The Government are still engaged in considering the matter, and it is to be hoped that they are receiving and giving heed to the counsel of their natural advisers, although, unfortunately, this is *a priori* extremely doubtful.

We print the letters addressed to the *Times* by Sir F. Bramwell, Mr. Poynter, and Sir J. Coode, and an account of the proceedings of the deputation on Tuesday.

It has for many years been recognized that the science collections at South Kensington are housed in a manner which largely diminishes their value for their principal use—viz. that in connection with the Royal Normal School of Science.

This school, as every one knows, is, as regards its main building, situated on the east side of Exhibition Road, while the collections are scattered about in the South Gallery and in the West Gallery adjacent to Queen's Gate.

In 1885 the Government appointed an inter-departmental committee to consider the subject and to report, and they nominated me, as being unconnected with any department, chairman of the committee. The committee (with one dissentient) reported in the sense that on the land lying west of Exhibition Road, and between that road and Queen's Gate, suitable buildings should be erected according to a complete design, but that they should be carried out in successive portions. Nothing was done on this report.

In 1889 another committee was appointed; this committee made very similar recommendations, and last year the Government acquired further land.

There are now on the west side of Exhibition Road, and immediately opposite the science schools, the observatories used by Mr. Norman Lockyer, and also a newly-erected physical laboratory.

Everything seemed to be, after all these years of waiting, in train for affording the needed accommodation, when, incredible as it must appear, the Chancellor of the Exchequer announced that the whole of this well-considered and satisfactory arrangement is to be given up. He stated it had been determined to sweep away the observatories and the physical laboratory, already on the west side of the road, and close to the science schools, and to devote this particular plot of ground to a picture gallery. I look upon this as a most disastrous proceeding, and one that, in the interest of the great National Department at South Kensington, should not be entertained for one moment.

Any one who will take the pains to visit the ground, or even to look at an accurate plan of it, will see that there is plenty of good space available for the picture gallery without interfering with the needs of the science collection, and that the notion of building it where proposed is so thoroughly preposterous that, as our American friends say, it must have originated in "pure cussedness."

Frederick Bramwell.

No. 5 Great George Street, Westminster, May 9.

Sir Frederick Bramwell in his letter of this morning points out the disastrous effect on the interests of the national Department of Science at South Kensington which will result from the intrusion of the new Gallery of British Art, to be planted precisely on the spot where it will cause the greatest amount of inconvenience. To an artist a still more flagrant instance of "pure cussedness" in this matter would appear to be that the building should be placed where it can have no connection with the existing galleries, when there is a piece of ground higher up the road in immediate connection with them.

The galleries on the east and west of the Horticultural Gardens, which were built for pictures at the time when there was a scheme for holding annual international exhibitions, are, whether by a happy "fluke" or by careful calculation on the part of their constructor, General Scott, without doubt the best lighted and the best proportioned picture galleries that have ever been constructed in England. Sir Frederick Leighton has, I know, expressed this opinion, and every artist who exhibited in these galleries during the three or four years that the exhibitions were held there will, I believe, agree in it: "We never saw our pictures look so well." These galleries are even now being connected by a building crossing the intervening space, the lower half of which will belong to the Imperial Institute, while the upper part is to be available for purposes of exhibition, thus making a connected group, and what would appear to be an unrivalled building for the purposes of a Gallery of British Art.

Why these buildings, acknowledged to be as good as they can be, and actually ready on the spot, should not be used for this purpose, according to what I understand was the original and nearly accepted scheme, it is somewhat difficult to understand. If the building for which £80,000 has been so liberally offered were placed higher up the road, above the Technical Institute, where there is a piece of ground available, it would back immediately on the Eastern Gallery, in which the Indian collection is now housed, thus affording provision for the extension of the collection, which is growing annually by the addition of the pictures purchased under the Chantrey bequest, and to which it is certain that further considerable additions will constantly be made by gift and bequest as soon as there is a place in which they can be properly and permanently exhibited.

Also, there is for once, if advantage be taken of it, an opportunity for carrying out a reasonable and consistent scheme for both science and art.

Edward J. Poynter, R.A.

28 Albert Gate, S.W., May 11.

Having served on the Committee on Machinery and Inventions in connection with the Science and Art Department of the Committee of Council on Education, I desire most emphatically to endorse the protest of Sir Frederick Bramwell which appears in your columns of this day's date.

Although the fees received from patentees up to the end of 1885 exceeded the expenditure of the Patent Office by upwards of 2½ millions sterling, nothing practically has been done to put the Patent Museum and Museum of Machinery and Inventions in an efficient condition.

Year after year the Committee, of which I am a member, has urged that more space should be given to the authorities at South Kensington, and now, when it was thought the recommendations were about to be realized, it is asserted that the promised site is to be devoted to a picture gallery.

I sincerely trust that this intention may not be carried out, but that the site in question, which exactly faces the Royal College of Science, will be appropriated for the science collections, to which purpose it has long been assigned.

Jno. Coode, President.

The Institution of Civil Engineers, 25 Great George Street,
Westminster, May 11.

The deputation which waited upon Lord Cranbrook, the Lord President of the Council, and Mr. Goschen was large and representative. Mr. Plunket, M.P., First Commissioner of Works, was also present. Among the deputation were: Sir William Thomson (President of the Royal Society), Sir Bernhard Samuelson, M.P., Sir George Gabriel Stokes (Past President of the Royal Society), Mr. C. Acland, M.P., Sir Frederick Bramwell, F.R.S., Prof. Story-Maskelyne, M.P., Sir Douglas Galton, C.B., Mr. Poynter, R.A., Prof. Unwin, Mr. Francis

Galton, Prof. Ayrton, Prof. Flower, C.B., Prof. Armstrong (Secretary of the Chemical Society), and Mr. Fletcher and Mr. Woodward, of the British Museum.

Prof. Story-Maskelyne, in introducing the deputation, in the absence of Sir Henry Roscoe (who is laid up with influenza), said it embraced a body of gentlemen distinguished not so much by their numbers as by their character, representing as they did the Royal Society and the scientific men of England. They had come there to ask that the question of the site of the new National Gallery for British Art should be reconsidered. Those who were deeply concerned in what he might call the new University which had risen for science at South Kensington felt that the proposed building would be a wedge put in between the place now occupied by it and the place dedicated to science. Scientific men would have to go across the road to get to another and interesting branch of the National Science Collection in a portion of the ground which would then be considerably remote from where they at present were. They understood it to be very much a question of money, and it was believed that the Government would have to ask Parliament to supplement the grant of £80,000 given by the anonymous donor. What he asked was that they should not be told offhand that the scheme could not be altered, but that they should be allowed to take the sense of Parliament as to whether the site was to be occupied in the way proposed or not. They objected to the money being simply asked from Parliament and the control taken out of its hands.

The Chancellor of the Exchequer.—You may entirely exclude that. That will not be done. We shall take such precautions by trustees and by contracts that such a contingency will not occur.

Prof. Story-Maskelyne said he was very glad to hear that.

Sir William Thomson, on behalf of the Royal Society, said they respectfully protested against the proposal to take the site now occupied by the physical laboratory of the Royal College of Science for any other purpose. Sixty pupils were now actively engaged. There was also a mining school in the same locality. No other sites could be as convenient as the site which those departments at the present occupied. It would be most fatal to the science work if the present arrangements were interfered with or the scientific collections, so conveniently arranged, were disturbed. Nor would the proposed site be the most convenient one for the pictures. A far better one would be that at present occupied by the School of Cookery, which, while affording ample room for the present proposal, would also be perfectly convenient for subsequent expansion in a direction that would result in the most admirable collection of picture galleries in the world.

The Chancellor of the Exchequer.—Can you tell us—for I have not yet been able to make it out—in what way the proposed arrangement would be fatal to the work of the College of Science?

Sir William Thomson.—By cutting the school in two—by separating the school from the place in which the instruments are kept.

The Chancellor of the Exchequer.—You mean that it is too far to walk?

Sir William Thomson.—It would be dreadfully risky to have to carry about delicate instruments.

Sir Bernhard Samuelson, as a member of a departmental committee which considered the question of housing the College of Science, supported Sir William Thomson's views, and pointed out that already there had been an encroachment upon the land which had been acquired for the purposes of the Science Museum.

The Chancellor of the Exchequer.—It was purchased for science and art. You do not contend that the whole of it should be devoted to science?

Sir Bernhard Samuelson said he did. He would like to ask the Chancellor of the Exchequer, after the assurance which he had just given that there would be no occasion to go to the House of Commons for a vote in aid of this work, whether he meant that, if there should be an expansion of the art gallery, some one would be ready to extend the munificence of the present donor.

The Chancellor of the Exchequer.—I think that that is rather a matter for our grandchildren. I think there is plenty of space to fill with worthy pictures for a very long time to come.

Prof. Story-Maskelyne.—But £80,000 will not do it.

Sir B. Samuelson said he hoped the question of the site would be reconsidered, and that those representing science should have the assurance that ample space would be given them not only for their present requirements but also for the extension which appeared to be looming in the future.

The Chancellor of the Exchequer.—I am anxious to provide well for science. We hope to bring science into one centre fronting the Imperial Institute.

Sir B. Samuelson said that if they were given an area equal to the amount purchased last year for the purpose of science alone they ought, in his opinion, to be content. But already there had been a small encroachment, and the fact of their having no actual claim to the ground would lead to further encroachment, which would, in the end, make it impossible for science to be efficiently provided for.

The Chancellor of the Exchequer.—I am anxious to show you that, quite irrespective of my interposition, we have not been blind to the interests of science, and that one of our plans has been to satisfy science in the most ample manner for the future.

Sir B. Samuelson said the art gallery was looked upon with a great deal of jealousy, and in the next place they feared that the full area of 200,000 feet, which they considered to be absolutely necessary for the future requirements of science, would be encroached upon.

Sir Frederick Bramwell, who was chairman of the departmental committee which considered the question in 1888, said there was a site to the north of the City and Guilds Institute, and from the east to the west there were galleries, and a cross gallery was being made by the Imperial Institute which would give communication one with the other, and which would be in immediate connection with the site he suggested. That would be an admirable art gallery. He would be glad to see the Science School and everything belonging to it moved so that there might not be a road dividing it. He trusted that the anonymous donor might be induced to see that his gift would prove more graceful if he did not impose a condition that would have so prejudicial an effect as would be the case if the recommendations of the two committees he had referred to were disregarded.

Lord Cranbrook.—The question, of course, so far as it can be considered will be considered, and I quite agree with Sir Frederick Bramwell that nobody can predict what may be done hereafter. You may have a scheme which, in itself, is a good one, but which may possibly have to wait. But in the meantime I can assure you that the interests of science will be most carefully considered, and that we will do what we can in order to further them.

Prof. Story-Maskelyne, having thanked Lord Cranbrook and Mr. Goschen for the hearing that had been given to their views,

The deputation withdrew.

We have received the following communication on this subject:—

Sir,—The curious admissions made by Mr. Goschen to the deputation which waited upon him and the Lord President indicate very clearly that we have, in the present muddle touching the site of the Art Gallery, another of those instances in which we suffer from the system, or, rather, want of system, which is characteristic of the relation of Government to science, and from the absence of scientific knowledge in those branches of the public service by which matters of the highest scientific moment are settled. A reference to some of the facts will, I think, show this very clearly.

The particular site which has been allocated by the Government in this way for the purposes of an art gallery forms part of a piece of land which, as is well known, only last year was deliberately purchased by the same Government for scientific purposes—to be quite accurate for "science and the arts"—that is, science and its manifold applications. *The space of ground thus purchased was less than half the space allotted to the Natural History Museum.* I say deliberately, because the purchase of the land in 1890 had for its object the carrying out of one of the recommendations of the Duke of Devonshire's Commission, which dates from the year 1874—namely, the erection of a Science Museum.

This object so warmly commended itself to the Royal Commissioners of the 1851 Exhibition that in 1876 they offered the land on which the Imperial Institute is now being erected and a sum of £100,000 towards its realization. Few acquainted with the manners and customs of our Government Departments in relation to science will be surprised to hear that this magnificent offer was refused; and it is to prevent a like disastrous mistake being now made that the strong memorial was presented to Lord Salisbury.

The ideal arrangement for a great national collection of scientific apparatus which is to do for the sciences of experiment and observation what the British Museum does for literature and antiquities, the Natural History Museum for biology, and the National Gallery for art, is that it shall be in close connection with laboratories where the apparatus can be used, presided over by experts who are familiarly acquainted with its construction and uses.

This was the ideal recommended to the Government by the Duke of Devonshire's Commission in 1874, and such is the ideal now being carried out by several of our provincial Colleges.

As all Londoners know, at present the Science Schools and the collection of scientific apparatus, which are both necessary for the realization of this scheme, are placed one on the east side of Exhibition Road, and the other chiefly in the Western Galleries. If the apparatus is employed in teaching, it must necessarily be transported about a quarter of a mile and back from the one to the other. And this accounts for the strange processions occasionally met in the neighbourhood of the Museum carrying delicate apparatus along the street alike in wet and dusty weather.

When the new piece of land was purchased last year on the recommendation of a very strong Treasury Committee, it was naturally expected that, as the overcrowded state of the existing school buildings rendered immediate action imperative, plans would be at once drawn up for an extension in the closest possible contiguity with the present building—that is to say, on the part of the newly-acquired plot immediately fronting it.

It was also believed that the Science Museum would be built in close and organic relation with the new laboratories, and that a scheme would be initiated which would supply pressing needs, and could, in course of time, be developed into the ideal institution which has been sketched.

These plans, to the carrying out of which the friends of science confidently looked forward, would be rendered absolutely futile by the grant for art purposes of the particular plot the alienation of which from the use for which it was purchased will render the objects of its purchase nugatory.

All hope of a compact site, therefore, for the future worthy representation of physical science would disappear as the result of this action of the Government.

The public have a right to know who is responsible for this, and how far the scientific officers of the Science and Art Department have been consulted. If they have in any way been consenting parties, it seems probable that they will have a *mauvais quart d'heure* with their scientific brethren who have signed the memorial and who attended the deputation; if they have not been consulted, the whole transaction is a disgrace to our administrative system.

An idea of the *impasse* in which this decision has landed matters scientific at South Kensington was to be gathered from one of Mr. Goschen's replies as to the makeshift arrangements at first proposed:—

(1) The second half of the Science Schools is to be built somewhere at the back of the new Art Gallery. This at once prevents all close relationship between the two halves of the same institution.

(2) The scientific apparatus is to be distributed in galleries which, although built for artistic purposes, are not considered good enough for art.

These, I presume, are the Western Gallery, the present *terminus a quo* of the processions to which reference has been made, a corresponding Eastern Gallery, now occupied by the Indian Museum, and the upper part of a new gallery, also designed for art, situated between the Imperial Institute and the Royal College of Music. All these galleries are as far removed as the limits of the Government estate will permit from the Science Schools, with which they are supposed to be in organic connection.

It appears, therefore, that the provision to be made for the Science Museum, which ought to rank, and in the future must rank, with the British Museum, the National Gallery, and other like institutions, is that the two halves of the Science Schools are to be widely sundered, while any organic connection with the Science Museum is to be rendered impossible.

I do not think, Sir, I need occupy any more of your space with recent history; the whole question stands thus:—

(1) In our museum system Art, Antiquities, Literature, and Natural History are magnificently provided for.

(2) Science is not provided for at all in any permanent manner.

(3) During the last twenty years Royal Commissions, Treasury and Departmental Committees without number, and deputations, have pointed out this gap.

(4) Last year the Government bought, and the Royal Commissioners for the Exhibition of 1851 sold cheap, a plot of land to be used for this purpose, and for this purpose alone.

(5) The plot is less than half of that on which the Natural History Museum stands.

(6) The Government now barter away a large portion of this small site for a mess of pottage.

I am, Sir,
Your obedient servant,
F.R.S.

NOTES.

THE ladies' *soirée* of the Royal Society will take place on Wednesday, June 17.

ON Tuesday the Convocation of the University of London considered the Draft Charter drawn up by the Senate. A resolution to the effect that the scheme should be approved was moved by Lord Herschell, seconded by Sir Richard Quain, and supported by Dr. Pye Smith. Mr. Bompas, Q.C., Mr. R. H. Hutton, and others spoke on the other side. In the end the scheme was rejected, 461 voting against it, and only 197 recording their votes in its favour. The whole subject needs to be thoroughly reconsidered, as the question of the higher teaching, one of the points first insisted on, seems to be dropping out of view. To educationists this is, of course, the really important element of the subject; and it cannot be for ever tolerated that the existence of an Imperial Examining Board, because it has been wrongly named, should prevent the largest city in the world from securing educational advantages which have for centuries been possessed by many a small German town.

THE Government of New South Wales have granted for the purposes of the Sydney Biological Station a plot of land of two acres on the north shore of Port Jackson at a part where the littoral fauna is particularly rich, and where the conditions are in other respects highly favourable. The Royal Society have made a grant of £50 towards the cost of the proposed new station.

THE annual meeting of the German Ornithological Society is being held this year at Frankfort, and the attendance is somewhat larger than usual, as several ornithologists have stopped at Frankfort on their way to the Congress at Budapest. The subject of zoological nomenclature was considered on Tuesday, when a discussion on the rules proposed by Dr. Reichenow and Graf von Berlepsch ensued. The question will be further considered at the forthcoming Ornithological Congress at Budapest, where Dr. Reichenow will be the exponent in the systematic section.

THE *conversazione* of the Society of Arts will be held at the South Kensington Museum on Wednesday evening, June 17.

M. EDMOND BECQUEREL, son, and successor as Professor, of Antoine César Becquerel, died on Monday, in Paris, at the age of 71. He was the author of treatises on the solar spectrum, the electric light, magnetic phenomena, and other scientific subjects.

PROF. JAMES GEIKIE, of the University of Edinburgh, has been delivering a course of lectures at the Lowell Institute, Boston, on Europe during and after the Ice Age. The course began on March 13 and ended on April 10.

A SHOCK of earthquake was felt at Athens on Monday evening.

THE fourth summer meeting of University Extension and other students, to be held at Oxford in August, will be divided into two parts. The first part of the meeting will begin with an inaugural lecture by Mr. Frederick Harrison on Friday evening, July 31, and will end on Tuesday evening, August 11. The second part of the meeting will begin on Wednesday morning, August 12, and end on Monday evening, August 31. In natural science fifty-nine lectures will be delivered, and there will be classes for practical work in the University laboratory and observatory, &c. Among the scientific lecturers will be Mr. E. B. Poulton, Prof. A. H. Green, Mr. W. E. Plummer, and Mr. C. Carus-Wilson. Scholarships to the value of £120 have been offered by various gentlemen for the purpose of enabling University Extension students, who would not otherwise be enabled to afford it, to study for a short time at Oxford.

A GLASS case just placed in the Mammal Gallery of the British Museum contains a series of specimens of two of the largest species of Asiatic Wild Sheep, collected and presented to the nation by Mr. St. George Littledale, the well-known sportsman. Three of these represent Marco Polo's Sheep (*Ovis poli*) from the Pamir Range, and three of them the Ammon (*Ovis ammon*) of the Altai. These are, we believe, the first perfect specimens of *Ovis poli*, the finest and largest of all the Asiatic Sheep, that have yet been brought to England, the species been generally known only by its horns, which are remarkable for their enormous size and width.

THE Australasian Association for the Advancement of Science has published the Report of its second meeting, held at Melbourne in January 1890. The volume is edited by Prof. W. Baldwin Spencer. No one who glances over the volume can fail to recognize that the Association is likely to exercise a most important influence on the development of scientific research and thought among our kinsfolk in the Australasian colonies.

THE Ealing Microscopical and Natural History Society, of which the Rev. G. Henslow is President, has issued its Report and Proceedings for 1890. The Committee are able to record that the work of the Society proceeded quietly but steadily on the lines laid down in previous years; the evening meetings, the excursions, and the *conversazione* having all been held in their appointed seasons, and having had a full measure of success. Among the subjects brought before the evening meetings were "Adventures in Siberia," by Mr. H. Seebohm; "The Natural History of Malta," by the Rev. G. Henslow; "Diatoms," by Mr. E. M. Nelson; and "A Gossip on Mushrooms and Toadstools," by Dr. M. C. Cooke.

DURING the last fortnight, according to the Cairo correspondent of the *Times*, there have been in Upper and Lower Egypt large swarms of locusts, which have caused much alarm, as it is believed that they originate from eggs laid in the country last year. The damage done to the young maize, sugar, and cotton is as yet insignificant, though some individual growers have had to re-sow cotton patches which had been devastated. The provincial Mudirs have received orders to do everything in their power to secure the extermination of the locusts. The correspondent says that this is the most serious reappearance of an old Egyptian plague that has been recorded for about forty years.

A CIRCULAR relating to certain alterations in the Science and Art Directory for the session 1891-92 has been issued to managers of schools of science and art by the Lords of the Committee of Council on Education. The following is an outline of the alterations, so far as they refer to science, or to science and art together:—(1) Subject 6—Theoretical Mechanics—will be treated in two subdivisions: (*a*) the mechanics of solids, and (*b*) the mechanics of fluids—liquids and gases—payments being made on each subdivision as a separate subject. Subject 8—Sound, Light, and Heat—will be treated in three subdivisions in the advanced and honours stages, which may be taken, and will be paid upon, separately. The elementary stage will still include all three subjects, but the syllabus will be curtailed and rendered easier, especially in "Sound." (2) These subdivisions will not be considered as separate subjects in the interpretation of the rule which limits the number of subjects on which payments may be made on a student in any one year. (3) The number of National Scholarships in science to be competed for each year will be increased from 14 to 22. (6) In both science and art, the prizes of books, as distinguished from certificates, will be largely reduced in number, and only given in competition; those prizes which are now awarded simply on the student attaining a certain standard of excellence in the examinations being abolished. The time has passed when such prizes from a central authority, which entail a disproportionate cost and delay in administration, were justified by the necessity for stimulating science and art schools; and the Lords of the Committee of Council on Education are of opinion that the scholarships which will be substituted for them will be more useful. They trust that those interested in education in the several localities will themselves provide prizes of books for deserving students which may be useful to them in their studies.

ACCORDING to the Indian papers, a persistent effort is being made by the Geological Department of the Government of India, in association with the Burmah Government, to explore the tin resources of Tenasserim. The flourishing condition of the almost adjacent Malay States of Perak and Selangor, which are under British protection, is mainly due to the income derived from tin royalties. A year ago an expert was borrowed from the Straits Settlements and placed in Tenasserim under Mr. Hughes, of the Geological Department. The party has this year been joined by Dr. Warth, the officer who did very good work for the Government in the Punjab salt mines; and Dr. King, the Director of the Department, has left Calcutta for an inspection of the survey operations which have been conducted during the last twelve months. It is now two years since the Chief Commissioner of Burmah sent a special officer to report on the tin mines of the Straits Settlements, and the present explorations are being conducted in pursuance of the recommendations then made.

A PASSAGE in the correspondence of Leibnitz and John Bernoulli, to which Prof. Hellmann has recently called attention in the *Meteorologische Zeitschrift*, indicates that Leibnitz conceived the idea of the aneroid barometer, which was first practically realized by Vidi in 1847. Bernoulli, early in the eighteenth century, was considering the phosphorescence of mercury in the barometer, and the possibility of making a new instrument which would give the variations of air-pressure on a larger scale; also the idea of a barometer for travellers; and Leibnitz tells him he had thought of a portable barometer, without mercury, in which a metallic case should be compressed by the weight of the air. A bladder, or leather case, which he also suggested, Bernoulli considered would be too hygroscopic.

MESSRS. MACMILLAN AND CO. have just published "Natural Selection and Tropical Nature—Essays on Descriptive and Theoretical Biology," by Mr. Alfred Russel Wallace. The volume consists mainly of a reprint of two well-known volume of essays—"Contributions to the Theory of Natural Selection," and "Tropical Nature and other Essays." Several essays have been either wholly or in part omitted. On the other hand, the author has included essays on the antiquity of man in North America, and on the debt of science to Darwin, which have hitherto been accessible only in the periodicals where they originally appeared. The text has been carefully corrected, and some important additions have been made.

A SUPPLEMENT to Dr. T. Lauder Brunton's "Text-book of Pharmacology, Therapeutics, and Materia Medica" has been issued by Messrs. Macmillan and Co. It presents the additions made in 1890 to the British Pharmacopœia of 1885. Although the medicinal substances contained in the British Pharmacopœia of 1885 are considered in the body of the work under the natural divisions of the mineral, vegetable, and animal kingdoms to which they belong, the author thinks it is easier to remember the additions by grouping them together according to their uses. A complete alphabetical list of them is also given.

A "BOTANICAL ADDRESS-BOOK" has been issued by the well-known Leipzig publisher, Wilhelm Engelmann. It contains a list of living botanists, and of botanical institutions, societies, and periodicals.

F. A. BROCKHAUS, of Leipzig, has issued a catalogue of scientific works which are offered for sale at his establishment. It includes, besides books, a large number of scientific periodicals and the publications of many learned societies.

THE 92nd and 93rd Parts of the "Länderkunde von Europa," edited by Alfred Kirchhoff, have been published. They present an excellent account of various parts of the Balkan Peninsula.

WILLING'S (late May's) useful "British and Irish Press Guide" for 1891 has been published. This is the eighteenth annual issue.

THE first number of a monthly journal for civil, mechanical, and electrical engineers, was published last week. The new journal is called the *Engineering Review*, and is edited by Mr. H. C. E. Andrée and Mr. Edward Walker.

AT the meeting of the Linnean Society of New South Wales on March 25, the Rev. Dr. W. Woolls read a paper on the classification of Eucalypts. After critically reviewing the characters of Eucalypts which have, from time to time, been made use of for classificatory purposes, more particularly those of the anthers and of the bark as set forth in the anthereal and cortical systems of Bentham and Mueller, the author suggested the probable value of a classification based on the characters of the fruit—such as shape, position of the capsules, the number of cells, and the appearance of the valves, &c.

CAPTAIN PETERSEN, of the Swedish barque *Eleanora*, noted a submarine earthquake in the volcanic region of the Atlantic west of St. Paul Rocks on March 13 between 7 and 8 p.m. According to a statement in the printed matter prepared for publication on the Pilot Chart of the North Atlantic Ocean for the present month, the ship was heading north-west, going about 3 knots, with a light easterly wind and calm sea, when a noise was heard on the port side, like a heavy surf, and almost immediately the sea began to bubble and boil like a huge kettle, the broken water reaching as high as the poop-deck. No distinct shock was felt, but after the disturbance struck the ship she continued to tremble as long as it lasted. After about an hour it ceased for an hour, and was then followed by another similar disturbance. A bubbling sound was all that could be heard, and the water appeared foamy, but it was impossible, on account of the darkness, to say whether it was muddy. The next day weather and sea were as usual. Position at 8 p.m., lat. 3° 47′ N., long. 42° 03′ W. The region from St. Paul Rocks to and including the Windward Islands is especially subject to earthquakes, and reports similar to the above are often received.

AT the ordinary meeting of the Institution of Civil Engineers on May 5, Mr. William Langdon read an interesting paper on railway-train lighting. He pointed out that the main questions to be determined were whether electricity was safe, trustworthy, and less costly than other illuminants. The fact that electrically-lighted trains had now been running for a considerable period without accident appeared to him conclusive evidence of its safety, and experience had shown that there was no reason to doubt its trustworthiness where efficient provision had been made; and he believed that when the cost of applying any of the illuminants, whether oil, gas, or electricity, to a complete railway system was taken into account the latter would be found the most economical. Regarding electricity as the illuminant which would, at no distant date, be universally employed for train lighting, Mr. Langdon suggested the desirability of arriving at a common basis with regard to the following fundamental points: (1) electrical system; (2) form and position of the electrical couplings; (3) pressure of current. Unless this was effected it was to be feared that unnecessary difficulties might be created by the diversity of the plans adopted.

MR. C. J. HANSSEN, a civil engineer of Copenhagen, has proposed a new international system of measures and weights, to which he invites our attention. He hopes that England will adopt his system, and that then the United States and Russia will follow, and thus the new system would become entirely international. Mr. Hanssen proposes that the English foot should be increased in length by about 1/2500th part of its present length (from 1·00000 to 1·000403); the pound avoirdupois, the ounce, and the imperial gallon, remaining unaltered. The cubic foot, as Mr. Hanssen states, would then contain exactly 1000 ounces of distilled water at 4° C.; and its intercomparison with the metric units of weight, length, and volume, would become apparently easy. We fear, however, that there is little hope in this country of introducing any such new system. As Mr. Chaney has indicated in his report on the Metric Conference, there are only two things possible in the metrology of this country: either to adhere to the present Imperial system, or to introduce the metric system. No half-way or modified Imperial system, such as Mr. Hanssen would propose, appears to be possible.

THE Deutsche Seewarte has published, in vol. xiii. of its *Aus dem Archiv*, a paper by Captain C. H. Seemann, one of the assistants in that establishment, entitled "Weather Lexicon: an Index to the European Weather Charts from 1876–1885." The author considers that the principles we at present possess for forecasting the weather—*e.g.* Buys-Ballot's law, the relation of the tracks of depressions to the distribution of pressure and temperature, or the dependence of the lower air-currents upon the upper currents—are not sufficient for the purpose, and he has made an index of the various similar types of weather-charts. He has calculated the barometrical differences which occur each day in three directions: (1) from Hamburg towards the north-west (Stornoway); (2) from Hamburg to the south-west (Biarritz); and (3) from Hamburg to the north-east (Helsingfors); and, by knowing the difference for any day, a reference to a table of such differences shows the dates of other charts with similar conditions, so that, by selecting one which appears most suitable to the present conditions, we may judge of the probable weather from that which actually followed that particular type. In the paper in question, only barometer and wind have been taken into account; the distribution of temperature would, of course, have great influence upon the changes of weather, but the author preferred to postpone the consideration of that element in this primary classification.

In the new number of the Journal of the Bombay Natural History Society, Lieutenant H. E. Barnes continues his interesting papers on nesting in Western India. Speaking of house-sparrows, he says that no amount of persecution seems to deter them from building in a place when they have once made up their minds to it. At Deesa, he found that a pair had built a large nest in the antlers of a sambur in the veranda. Another pair made a nest in the soap-box in the bath-room, and although the nest was destroyed several times, they would not desist, and at last, "from sheer pity," he had to leave them alone. The most peculiar case was when a pair had a nest in a bird-cage hanging against the wall, just above where the "durzi" sat all day working, and close to a door through which people were passing in and out continually. The door of the cage had been left open, the previous occupant having been transferred elsewhere. Not only were four eggs laid, but the nestlings were reared, although the cage was frequently taken down to be shown to visitors. Once the eggs were nearly lost, a boy having taken them out. The fuss made by the birds led to the recovery of the eggs. The author has a curious note on another peculiarity of sparrows. "I have often," he says, "had to turn the face of a looking-glass to the wall to prevent them from injuring themselves, for immediately one of them catches a glimpse of himself in it, he commences a furious onslaught on what he imagines must be a rival, and, if not prevented, will continue fighting the whole day, only leaving off when darkness sets in, recommencing the battle at dawn the next day. I once tried to see how long it would be before the bird gave in, but after two days, seeing no likelihood of his retiring from the unequal contest, I took pity on him and had the glass covered up. The bird did not seem in any way exhausted, although I do not think that he had a morsel of food for two days."

Some remarkable electrical phenomena accompanying the production upon the large scale of solid carbon dioxide are described by Dr. Haussknecht, of Berlin, in the current number of the *Berichte* of the German Chemical Society. In order to obtain large quantities of solid carbonic acid it is found most convenient in practice to allow the liquid stored in the usual form of iron cylinder to escape into a stout canvas bag, best constructed of sail-cloth or some such strong fabric, instead of the usual lecture-room receiving apparatus, the cylinder being inclined from the vertical so as to permit of a ready and uniform exit from the opened valve. The liquid under these circumstances issues at pressures varying from 60–80 atmospheres, and a compact snow-like mass of solid carbon dioxide is formed in the canvas receiver, owing, as is well known, to the extreme lowering of the temperature of the liquid due to its sudden expansion and the accompanying absorption of heat. When the experiment is performed in the dark, the canvas receiver is seen to be illuminated within by a pale greenish-violet light, and Dr. Haussknecht states that electric sparks 10–20 cm. long dart out from the pores of the cloth. If the hand is held in these sparks the usual pricking sensation is felt, similar to that perceived on touching the conductor of an electric machine at work. Dr. Haussknecht further states that the phenomenon is very noticeable in the dark whenever there is a leakage in any portion of the compressing apparatus or the manometers connected therewith. The reason assigned for this development of statical electricity is similar in principle to that usually accepted in explanation of the hydro-electric machine of Sir William Armstrong. As the liquid carbonic acid is issuing from the valve it becomes partly converted into gas which is violently forced through every pore of the canvas. Moreover, carried along with this stream of gas are great quantities of minute globules of liquid, which are brought in forcible contact with the solid particles already deposited. Dr. Haussknecht therefore considers that the electrical excitation is due mainly to the violent friction between these liquid globules and the solid snow. It is very essential for the successful reproduction of these electrical phenomena that the carbon dioxide should be absolutely free from admixed air; that prepared artificially yielding much finer results than that obtained from natural waters, which latter contains considerable quantities of air. The luminosity is not generally developed in the interior of the receiver until a crust of solid carbonic acid 0·5–1 cm. thick has been deposited, which renders the probability of the correctness of the above theory all the greater. Dr. Haussknecht has constructed a special form of apparatus, with which he is now experimenting, with the view of being able to determine the sign, nature, and quantity of the generated electricity.

The additions to the Zoological Society's Gardens during the past week include two Brown Capuchins (*Cebus fatuellus* ♂ ♂), an Ocelot (*Felis pardalis*), a Coypu (*Myopotamus coypus*), two Ring-tailed Coatis (*Nasua rufa*), two Cayenne Lapwings (*Vanellus cayennensis*), seven Burrowing Owls (*Speotyto cunicularia*) from South America, presented by Mr. James Meldrum; a Pig-tailed Monkey (*Macacus nemestrinus* ♀) from Java, presented by Mr. C. Powell; a Common Hare (*Lepus europæus*), British, presented by Mr. H. T. Bowes; three Pintails (*Dafila acuta* ♂ ♂ ♀), European, a Mandarin Duck (*Æx galericulata* ♀) from China, presented by Mr. G. F. Mathews, R.N., F.Z.S.; a Common Boa (*Boa constrictor*) from South America, presented by the Directors of the Museum, Demerara; two Cheer Pheasants (*Phasianus wallachii* ♂ ♀) from Northern India, twelve Common Teal (*Querquedula crecca*, 4 ♂, 8 ♀), European, purchased; a Viscacha (*Lagostomus trichodactylus*), a Red Kangaroo (*Macropus rufus*), born in the Gardens.

THE IRON AND STEEL INSTITUTE.

On Wednesday and Thursday of last week the annual spring meeting of the Iron and Steel Institute was held. The gathering was announced to extend over Friday also, but for some reason, best known to those who had the control of the meeting, the second day's proceedings were so hurried through that all the business was disposed of by half-past one o'clock on the second day; no less than six papers being taken at the one sitting. Naturally there was very little discussion; and indeed the second day of the meeting might almost as well have been dispensed with, and copies of the papers given to members to take home to read at their leisure. It is seldom that we have been present at a duller gathering than that which the meeting became towards its close, there not being a dozen members present to hear the Secretary hurry through the papers one after another, the President apparently being only anxious that there should be no discussion to prolong the proceedings.

The following is a list of the papers read:—On the manufacture of war material in the United States, by Mr. W. H. Jaques, of Bethlehem, U.S.A.; on tests for steel used in the manufacture of artillery, by Dr. Wm. Anderson, Director-General of Ordnance; on certain pyrometric measurements and the method of recording them, by Prof. Roberts-Austen, F.R.S.; on the changes in iron produced by thermal treatment, by Dr. E. J. Ball, London; on a graphic method of calculating the composition of furnace charges, by Mr. H. C. Jenkins; on economical puddling and puddling cinder, by Prof. Thomas Turner, Birmingham; on the micro-structure of steel, by M. Osmond, of Paris. There were three other papers which were not read.

Upon the members assembling in the theatre of the Institution of Civil Engineers, which was lent for the occasion by the Council of the latter Society, according to their hospitable custom, Sir James Kitson, the retiring President, occupied the chair. After the usual formal business had been transacted, the new President, Sir Frederick Abel, F.R.S., was duly installed, and at once proceeded to deliver his inaugural address. Sir Frederick is also this year President of the British Association, and should spend a busy autumn attending both the meeting of the Iron and Steel Institute in Birmingham, and of the Association in Cardiff. The address was of considerable length, embracing a wide range of subjects and a long span of time. The duration of Sir Frederick Abel's official life has been long, exceptionally long for the years he has lived, for he obtained employment in the Government service at an early age. It was shortly after the outbreak of the Russian War that he succeeded the illustrious Faraday in the Professorship of Chemistry at the Royal Military Academy, and since then he may be said to have seen almost the whole history of the birth and subsequent growth of applied science in connection with the industries of iron and steel making. At the beginning of his career, he tells us in his address, those who, in this country, appraised at their proper value the services which the analytical and scientific chemist could render to the iron-master and manufacturer of steel might be counted on the fingers. Systematic mineral analysis was just in process of application, volumetric analysis was altogether in its infancy, and spectroscopic analysis was not even dreamt of. The metallurgic operations in the Arsenal at Woolwich were limited to the production of small castings of brass for fittings of gun carriages, and to the casting of bronze ordnance for field service. Our supplies of cast-iron ordnance for siege and naval use were drawn from a very few of our most renowned iron-works, and our shot and shell were exclusively supplied from private works. What Woolwich has become since those days—and in spite of its faults of administration it is something of which the country may be proud—and how large a part Sir Frederick has borne in this development, most of our readers must be well aware. In those days our most powerful guns were 8-inch smooth bore 68-pounders of cast-iron, weighing 95 hundredweight, and fired with a charge of 18 pounds of powder. Now we have the 110-ton breech-loading rifled gun, built up of steel hoops and tubes, the calibre of which is 16¼ inches, and which throws a steel projectile weighing 1800 pounds with a powder charge of 960 pounds. Notwithstanding the fact that the 110-ton gun is in advance of its time—our mechanical skill and engineering knowledge not yet being sufficient to properly carry out the design—it would be difficult perhaps to find a more striking example of the application of scientific principles to the industrial arts; although we must not forget that the credit of the advance is due rather to Elswick than to Woolwich.

Leaving the region of historical retrospection, the address makes reference to the proposal of Prof. Langley, of Michigan University, made at the last Bath meeting of the British Association, that a series of samples of steel should be distributed between the metallurgical experts of different countries, in order that they might be analyzed and a part deposited as standards in each of the countries. The sets of samples supplied to each country were to be identical in composition, but each set would contain specimens varying in composition. The results of the analyses were to be compared, the object being to promote greater uniformity of procedure and a selection of the best methods. The Crescent Steel Works of Pittsburg have supplied the samples, and the English experts have almost completed their work. Should the Commission succeed in bringing about uniformity of practice in this respect, it will do much towards lightening the work of those who have to compare the results arrived at in different countries. Sir Frederick next referred to Dr. Sorby's method of examination of iron and steel by microscopic examination of carefully prepared samples, in which the structure has been developed by treatment with a weak acid. It will be remembered that Dr. Sorby gave a description of his process in a paper read before the Iron and Steel Institute two or three years ago; and since then Dr. Herman Wedding has followed the matter up with success. Many years previously Faraday had pursued an analogous course of investigation. It is satisfactory to learn that "the systematic application of Sorby's system of microscopic examination of prepared surfaces of steel and iron is continually extending at the German works, and that many series of experiments have demonstrated that by this system of examination characteristic features of grades of iron may be discovered, physical differences co-existing with identity of chemical composition explained, and evidences of the true grounds of disasters obtained." A very interesting subject next occupied a place in the address. This was the self-destruction, if one may use the term, of steel projectiles by the development of cracks. It is well known that steel projectiles may be received from the manufacturer to all appearance perfectly sound, and after a time cracks will develop themselves. In extreme cases the occurrence has been so sudden that a violent rupture, attended by a sharp report, has taken place. The cause doubtless is the surface treatment to which the shot is subjected in order to get the requisite hardness, and which leads to internal strains being set up. In one case mentioned in the address the head of the projectile had been thrown to a distance of many feet by the violent spontaneous rupture of the metal. The importance of rest in bringing about a diminution, if not entire disappearance, of internal strains in masses of metal is illustrated by the behaviour of chrome steel projectiles, which had to be stored for several months before their transport to a distance could be ventured upon. In connection with this subject Sir Frederick referred to a previous report in which he dwelt upon the effect of time in establishing chemical equilibrium in masses of metal. He also quoted a letter written to him by Thomas Graham, when Master of the Mint, in which was discussed the tendency to the development of cracks in tempered steel dies, and stating that in the Mint it was generally considered that if such dies were kept in store for a year or two, they became less apt to crack when in use, and coined more pieces than dies newly tempered. The same phenomena have to be considered in the manufacture of steel ordnance; and an instance was given by the lecturer of the tube of a large gun which had fired three proof rounds. A circumferential crack was found to have become developed in the front threads of the breech screw, and, upon removing the jacket from the tube the crack extended forward along the chamber and into the rifling. When the tube was placed in the lathe, with a view to cutting off the injured portion, the crack suddenly developed itself with a loud report, and ran along to within eight feet of the muzzle; a spiral crack at the same time ran completely round the tube, which fell in two upon removal from the lathe. This instance will strengthen the hands of those who are opposed to oil-hardening the parts of a steel gun; and Sir Frederick's own words in connection with this vexed question are worth quoting. "One effect which the oil-hardening treatment has occasionally exercised in the case of particular qualities of steel is that of developing minute fissures or cracks in the metal, either superficially or in the interior of the mass. This cannot, of course, be rectified by any annealing process, and it is still a question, to be determined by the teachings of experience and the result of investigations, whether any definite or reliable modifications in the composition of steel used for guns, tending to secure the desired combination of hardness and tenacity may not be introduced, with the result that a method of treatment of the metal may be discarded which, however carefully applied, and however efficient the means adopted for reducing or neutralizing its possible prejudicial influence upon the physical stability of the parts of which a gun is built up, carries with it inherent elements of uncertainty and possible danger." Dr. Anderson's remarks on the subject of oil-hardening should also be read in connection with the observations contained in the President's report. On the whole, perhaps, it would not be rash to predict that the days of this process are numbered in connection with the manufacture of steel ordnance for Her Majesty's service. For a long time many of our best authorities have been opposed to it.

We have not space to follow the address into the subject of the effect of silicon in cast-iron. General interest in this matter was aroused a year or two ago by a paper read before the Iron and Steel Institute by Thomas Turner, of Mason's College; and since then the investigation has been followed up by German experimentalists, with a general result that, under certain conditions, it is concluded that silicon will contribute to the production of dense and homogeneous castings.

The following passage from the address speaks for itself. It would be well if it could be printed and distributed to every British iron or steel maker:—

"The absolute dependence of the development of new metallurgic processes upon the results of the labours of the analyst, the chemical investigator, the physicist, and the microscopist, and the thoroughness with which this all-important fact is appreciated by the German metallurgic establishments, afford new occasion for a regretful recognition of the distance which we are still behind our Continental brethren in availing ourselves of the advantages afforded by the constant pursuit of scientific research, and the thoroughly efficient, systematic, and direct application of the labours of the scientific investigator to the daily operations at works of all kinds, although it must be acknowledged that of late years we have made important progress in these directions. It has certainly been humiliating to have to admit that industries which the genius of individual

Englishmen, possessed of exceptional powers of applying to important practical purposes the results of research, have created and have developed to an extent foreshadowing their high importance, gradually passed out of our hands through the far-sightedness of the Germans, who have very long since recognized the absolute dependence of progress in such industries upon the constant pursuit of chemical research into the far-reaching and continually spreading ramifications of organic chemistry. Thus, in fields of work, where, in days past, and even of late, our industrial chemists have been content to pursue their attempts at progress with the co-operation of one or two young chemical assistants, small armies of highly-trained chemists, who have gained academic honours, and have won their spurs in original investigation, are in constant employment at the magnificent manufacturing establishments in Germany, systematically pursuing researches which constitute successive indispensable links in a great network of exhaustive inquiry, and which, while conferring large benefits on the science itself, are continuously productive of improvements in existing processes, or of the development of new methods, while, ever and anon, they result in some fresh discovery of great technical importance and high commercial value. Similarly elaborate and comprehensive arrangements now exist at important German iron and steel works for systematic investigation and comparison of materials of products and processes."

We must hurry over the remaining parts of Sir Frederick's address, and can only mention some of the chief subjects touched upon, referring our readers to the Proceedings of the Institute for fuller information. Thus we find the following matters occupying attention: the presence and effect of nitrogen in iron; the state in which carbon exists in steel; Osmond's study, by means of the Le Chatelier pyrometer, of the slow cooling of iron and steel, together with the phenomena of recalescence, and the existence of two allotropic forms of iron; the effect of aluminium in iron; Hadfield's researches in connection with manganese steel; the progress of nickel steel; and the interesting discovery of Langer, Quincke, and Ludwig Mond of the action of carbonic acid upon finely divided nickel at high temperature, in which it was found that the metal had the power of separating carbon from the gas, with production of carbonic acid in place of the oxide. These and other matters were dealt with at greater or less length, and constituted a most interesting and characteristic address.

Only one paper was read on the first day of the meeting. This was Dr. Anderson's contribution on tests for steel used in the manufacture of artillery. The announcement of a contribution on this subject by the Director-General of Ordnance Factories had caused a good deal of interest both among the scientific and manufacturing members of the Institute, more especially as it was known that the Government authorities had been overhauling the official test regulations. Unfortunately, however, the meeting was a little too early, so far as Dr. Anderson's paper was concerned, for the new regulations have not yet been officially published, and, until they are, it is against official etiquette, if not official rules, that they should be made known. The paper was therefore very like the play of "Hamlet" with the Prince of Denmark left out, and bore evidence of having been brought forward rather with a view of fulfilling a promise than because the author had anything new to advance. It was not Dr. Anderson's fault that his paper was robbed of its chief interest, and certainly the thanks of the Council were due to him for good-naturedly allowing it to stand on the programme. Notwithstanding what we have said, the paper was very interesting, but as we hope to hear Dr. Anderson again on the subject, when the official veto has been removed by publication of the new tests, we shall treat the matter briefly. It is first pointed out that the mechanical properties of steel, and of alloys generally, are affected in a remarkable manner by extremely minute quantities of substances, by the relative proportions, by the changes in some or all, produced by the more or less rapid changes of temperature, which influence dissociation and reveal their effects by recalescence; indicating, to a less degree, allotropic changes in some or all of the components. Chemical analysis sufficiently minute to detect even traces of every substance associated with iron would be tedious and costly. Years must pass away before chemical and physical science together will succeed in determining the laws which govern the mechanical properties of alloys. For these reasons, and others, the specifications of gun-steel used in Her Majesty's service exclude all definitions of chemical composition, so far, at any rate, as ordinary ingredients are concerned. The author thinks it is not sufficiently realized that metals are incapable of appreciable cubical compression under any stress that can in practice be brought to bear on them, whether fluid, pasty, or cold. Like ice and water, steel and cast-iron have a greater volume in a solid than in the liquid state, and, therefore, red-hot solid cast-iron or steel floats on the surface of the molten mass: although, it should be added, cold cast-iron will at first sink in a bath of liquid iron, but will rise to the surface and float when it has acquired a sufficient degree of heat to bring it about to a cherry red. This was shown by the well-known experiments of Mr. Wrightson, referred to at the meeting. The manner in which, during cooling, compressive stress is suddenly turned into tension high enough to cause rupture (due to the swelling during solidification) is dealt with; this being a subject also treated upon in the President's address. The bearing of these phenomena upon the process of hardening is also discussed. The relative influence of carbon in iron as a definite compound of carbon and iron dissolved in an excess of iron, and as a finely subdivided carbon diffused through the mass, is considered, and the author expresses an opinion that the "apparently capricious behaviour of steel" is due not only to the internal stresses engendered by oil-hardening, but also to the circumstance that the chemical condition of the steel and its molecular structure are greatly influenced by comparatively slight errors of judgment, or by carelessness in the adjustment of the temperatures at which the operations are performed.

A discussion followed the reading of the paper, in which the most interesting incident was Mr. Wrightson's description of his experiments to determine the volume of cast-iron at different temperatures. Mr. Edmunds, of Woolwich, defended the practice of oil-hardening for gun-steel; and Mr. Hadfield would attribute cracks in steel rather to contraction than expansion.

On the second day of the meeting the proceedings were opened by Prof. Roberts-Austen giving a verbal description of the Le Chatelier pyrometer, an instrument which is now well known to the scientific world. It may be of interest to state that Sir Lowthian Bell and other practical men spoke of the great assistance this pyrometer had been to them in the course of manufacturing operations.

M. Osmond's paper on the micro-structure of steel was no more than a note which accompanied the presentation of a series of micro-photographs. The paper of Dr. E. J. Ball, which followed, was supplemental to a previous paper contributed by him (see Journal Iron and Steel Inst., 1890, No. 1, p. 85); and, as the present paper will be supplemented by another, we will refer our readers to the Proceedings, merely giving the general conclusions arrived at by the author, which are as follows:—"(1) That in iron containing 0·1 per cent. of carbon, the tenacity of the metal increases by hardening, either in oil or in water, with the temperature at which the metal is quenched with a view to hardening, a maximum tensile strength being reached at a temperature of about 1300° C. This temperature once exceeded, however, the tenacity of the metal diminishes, although the extensibility increases. (2) By raising the percentage of carbon from 0·1 to 0·2, the maximum tenacity is attained, not at 1300° C., but at a much lower temperature—about 1000°—below the melting-point of iron oxide, which, moreover, was not present. (3) By further considerably increasing the percentage of carbon, this point of maximum tenacity apparently disappears almost entirely, the annealed metal having nearly as high a tensile strength as the same metal which has been quenched in oil from any temperature up to a bright red heat. Beyond this temperature, or when quenched in water, the hardened metal became so hard and brittle that it could not be gripped by the jaws of the testing machine." It will be remembered by those who attended the meeting when Dr. Ball's last paper was read that M. Osmond put forward the idea that the fourth point in change (in addition to Osmond's three points), which occurs, according to Dr. Ball, in very mild steel at a temperature approaching the melting-point, might be due to the fusion of iron oxide. The present paper is founded on this remark, but for the results, beyond the salient features given, we must, as we have said, refer our readers to the originals. Mr. Turner's paper, which was read next, does not require a detailed notice at our hands. It was an economic paper on a subject which is rapidly losing economic interest; and the author does not appear to have made himself well acquainted with the labours of previous investigators in this field. The paper of Mr. Jenkins does not admit of an abstract being made; whilst the last paper read, that of Lieutenant Jaques, U.S.N., was of such a voluminous nature that it might better be described as a treatise, and is far beyond our scope, as may be judged from its title.

The autumn meeting of the Institute will probably be held at Birmingham.

THE ROYAL SOCIETY SOIRÉE.

THE *soirées* given by the Royal Society become every year more pleasant. The one held on Wednesday, May 6, was in every sense most successful. We note some of the objects exhibited:—

Mr. J. Wimshurst exhibited an electrical influence machine (alternating and experimental).

The Trotter curve ranger was shown by Mr. A. P. Trotter. This portable instrument is intended to facilitate setting out large curves for railway and other work. It dispenses with tables of angles and with the use of chains and assistants. No cumulative error can arise as with theodolite work.

Profs, Rücker and Thorpe, FF.R.S., exhibited a map showing the probable connection of lines towards which the magnet is attracted in England and France. Profs. Rücker and Thorpe found that the north pole of a magnet is attracted to a line which runs south from Reading, and enters the Channel near Chichester. M. Moureaux has traced a similar line from Fécamp to the south of Paris, but its southern termination has not yet been discovered. The directions of the two lines make it probable that they are parts of the same axis of disturbance.

The Director-General of the Geological Survey exhibited:—(1) Specimens illustrating the phosphatic chalks in England, France, and Belgium, arranged by Mr. A. Strahan, Geological Survey of England and Wales. Phosphatic band in the upper chalk of Taplow, containing about 30 per cent. of phosphate of lime. Taplow phosphatic chalk separated by washing into: (1) brown sand composed of phosphatised organisms, and containing about 50 per cent. of phosphate of lime; (2) chalky mud composed largely of rhabdoliths, coccoliths, and discoliths. Microscopic preparations of the phosphatised organisms of the Taplow chalk, showing Foraminifera, prisms of Inoceramus shell, fish-scales, fish-bones, and fish-pellets. Photographs of the Taplow phosphatised organisms, by Mr. J. J. H. Teall, F.R.S. Phosphatic chalk of Beauval (Somme), and microscopic preparation. Phosphatic chalk of Ciply (Belgium), and microscopic preparation.—(2) Illustrations of a former Arctic climate in the Lowlands of Scotland, determined by Mr. Clement Reid, Geological Survey. At Hailes, about three miles south-west of Edinburgh, in a thin seam of silt, resting immediately on boulder clay, Mr. J. Bennil, of the Geological Survey of Scotland, has lately found numerous remains of plants. These show a climate probably 15° or 20° colder than that of the Lowlands at the present day. In the following list the peculiarly Arctic species are marked with an asterisk. The only *tree* is an alder. The willows are all dwarf species; two of them (*Salix herbacea* and *S. reticulata*) still live on the higher mountains of Scotland, the third (*S. polaris*) is an Arctic form now extinct in Britain. At the same locality there is another deposit, probably of later date, which contains only plants still living in the neighbourhood, including several trees.

Thalictrum
Ranunculus aquatilis
Viola
Stellaria media
Oxalis acetosella
Hippuris vulgaris
**Loiseleuria procumbens*
Menyanthes trifoliata
Stachys palustris
Ajuga reptans
Chrysanthemum Leucanthemum
Polygonum aviculare
**Salix herbacea*
**Salix polaris*
**Salix reticulata*
Alnus
Empetrum nigrum
Potamogeton
Eleocharis palustris
Scirpus pauciflorus
Scirpus lacustris
Scirpus?
Carex?
Isoetes lacustris

The Executive Committee of the Silchester Excavation Fund exhibited (by permission of the Duke of Wellington):—(1) Iron tools and utensils of the Roman period, found together in a pit in the Romano-British city at Silchester, Hants, in September 1890.—(2) Bronze objects of the Roman period found at Silchester.

Prof. H. Carrington Bolton, Ph.D. (of New York), exhibited musical sand, from Arabia, United States of America, and the Hawaiian Islands, collected by the exhibitor.

Prof. H. G. Seeley, F.R.S., exhibited remains of Anomodont Reptiles from the Trias, Karoo, Cape Colony.

The Director of the Royal Gardens, Kew, exhibited a collection of views in the Royal Gardens, Kew, showing the development of the Gardens during the last fifty years. This series is a portion of a very extensive and valuable collection of prints, drawings, and photographs of the most interesting features in the Royal Gardens. It has been brought together during the past twenty years, and is now deposited for exhibition in Museum No. 3.

Messrs. J. E. H. Gordon and Co. exhibited Tomlinson regulator for electric light mains. The Tomlinson regulator is intended for use in transformer sub-stations. It is worked by a wire from the central station, but automatically corrects any error of the attendant at the central station. Ordinary automatic apparatus cannot be safely used for this purpose, as, though should such get out of order when taking out transformers, no harm is done except the waste of coal, yet if it gets out of order when putting in transformers it may burn up the sub-station. The peculiarity of the new apparatus is that if anything whatever goes wrong, all transformers are at once put in, thus ensuring absolute safety. By the courtesy of the Brush Company, and of the Metropolitan Electric Supply Company, who have lent the necessary machinery, the apparatus has been tried on a large scale in the Brush Company's works. A plant of 1950 lights capacity has been run for 24 hours with, and for 24 hours without, the new apparatus, with the result of a saving of 4¼ cwt. of coal, or, in other words, with the new apparatus there was a saving of 89 pounds of coal per 8 c.p. lamp per annum, or about 26 per cent. of the total coal bill.

Sir J. B. Lawes, Bart., F.R.S., and Dr. J. H. Gilbert, F.R.S., showed:—(1) Three enlarged photographs of Leguminous plants, grown in 1889, in experiments on the question of the fixation of free nitrogen. The plants were grown, in some cases with sterilization, and in others with microbe-seeding of the soil. With suitable microbe-infection of the soil, there was abundant formation of the so-called *leguminous nodules* on the roots of the plants, and there was, coincidently, very considerable fixation of free nitrogen. The evidence at command points to the conclusion that the free nitrogen is fixed in the course of the development of the organisms within the nodules, and that the resulting nitrogenous compounds are absorbed and utilized by the higher plant.—(2) Coloured drawing, by Lady Lawes, of the Rothamsted rain-gauges.—(3) Coloured drawing, by Lady Lawes, of the Rothamsted drain-gauges.

Old plan of the Mint in the Tower of London, exhibited by the Hon. Sir C. W. Fremantle, K.C.B. This document is described as an exact survey of "The Ground Plot or Plan of His Majesty's Office of Mint in the Tower of London." It bears the date 170^{0}_{1}, and must have been prepared by the order of Sir Isaac Newton, who was appointed Master of the Mint in 1699. The position of Newton's official residence is shown at A.

Mr. R. E. Crompton, M.Inst.C.E., exhibited:—(1) Section of armature winding, showing copper divided, twisted, and compressed, to avoid loss from eddy currents.—(2) Crompton's method of obtaining accurately sub-multiples of the ohm; for current-measuring purposes.

Prof. Oliver Lodge, D.Sc., F.R.S., exhibited:—(1) Revolving mirror. Rapid revolving mirror driven by clock-work, with detachable fan to give moderate speeds, with adjustable main spring to vary the speed, and with vacuum cover for highest speeds (the last not yet satisfactory). Slow moving index, to enable the speed to be determined; and electro-magnetic brake to regulate its going, or to stop it gradually. Mirror, 2·3 × 1 cm., silvered back and front; very light, but giving fair definition. It makes 5760 revolutions for 1 of the winding arbor. Used for analyzing sparks, and observing the speed of electric pulses along conductors of various kinds. Made by Mr. W. Groves.—(2) Clock for pointing out continually the direction of the earth's orbital motion. (Two home-made forms.) A disk, or dial, set on a polar axis with the obliquity of the ecliptic, is driven by a clock against the rotation of the earth. On the dial are recorded 365 days of the year. It is set once for all in the plane of the ecliptic, with the actual date pointing 90° from the sun. In the first instrument I devised, the direction of the right-dated radius of the dial henceforth points out the direction of the earth's motion at any instant, if the clock keeps sidereal time. A modified and improved instrument, devised by my assistant, Mr. Edward E. Robinson, adds a sighted pointer to the dial, this pointer being moved by hand to the right date; and the clock may then keep ordinary time. The dial is geared down 1 : 24, and driven by the minute hand, so as to be under the ordinary control of clock-regulation. In each instrument a one-day hand-shift is needed every 29th February. —(3) Resonant Leyden jars. A couple of independent but similar Leyden jar circuits arranged at a moderate distance from each other, the self-induction or capacity of one of them being adjustable, with an easy overflow path. On discharging one of the jars, the other resounds and overflows, being provided with an easy overflow path. The oscillations are much more numerous than with ordinary linear (Hertz) vibrators, and therefore some precision is demanded in the tuning.

Self-recording instruments, exhibited by MM. Richard Frères.

Method of recording pyrometric measurements at temperatures between 600° C. and 1200° C., exhibited by Prof. Roberts-Austen, C.B., F.R.S. The apparatus is that employed in a research undertaken for the Institution of Mechanical Engineers, and is used for automatically recording, by the aid of photography, the indications of a platinum and platinum-rhodium thermo-couple. The experiments shown illustrate a method of recording the rate of cooling of heated masses of metal. Curves are shown to illustrate the kind of results which are obtained by the aid of the apparatus.

Length-measuring instrument, exhibited by Prof. W. C. Unwin, F.R.S. In ordinary screw or vernier micrometers the straining of the instrument alters the readings, and in using the instrument much depends on personal skill. In this instrument the contact is with fixed pressure, and independent of feeling. Delicate levels show when the instrument is adjusted.

Portraits of deceased astronomers and physicists, exhibited by Mr. W. B. Croft.

Mr. Killingworth Hedges exhibited:—(1) Electrical safety-valve.—(2) Exhausted bulbs, used to ascertain the space traversed by high tension alternating currents. The electrical safety-valve is designed for attachment to low pressure service lines, in order to prevent their being charged at a dangerous difference of potential from the earth. The glass bulbs were exhausted to different pressures, and fitted with electrodes of various forms, in order to ascertain if an arc could be started with an E.M.F. of 300 volts, which is the limit of potential fixed by the Board of Trade for currents of low pressure.

Focometer, exhibited by Prof. Silvanus P. Thompson. By this instrument can be determined the position of the two principal "focal planes" and of the two "principal planes" of Gauss, for any compound system of lenses, such as a microscopic objective or the lens of a photographic camera; thus giving the true focal length, and the positions and distance apart of the two virtual optical centres of the lens-system. The principle applied is that of finding directly the two principal foci, and then, by means of a right-and-left-handed screw, moving two micrometers placed at these foci to the two symmetric points where each micrometer coincides with the image of the other. The displacement so given by the screw is equal to the true focal length.

Mr. Shelford Bidwell, F.R.S., exhibited: (1) Selenium cells, the electrical conductivity of which is greater in the light than in the dark. (2) A selenium lamp-lighter, lighting an incandescent lamp automatically when darkness comes on. (3) A selenium alarm, for calling attention to the accidental extinction of a ship's light or railway signal lamp.—Mr. W. Crookes, F.R.S., exhibited electricity and high vacua.—Mr. G. J. Symons, F.R.S., exhibited photographs of damage produced by the tornado of August 18, 1890, at Dreux (Eure et Loire), France. —Prof. C. Piazzi Smyth exhibited examples of photographic enlargements of the solar spectrum, each magnified from the original negative from 25 to 27 times linear.—Mr. George Higgs exhibited photographs of the normal solar spectrum.

M. G. Lippmann exhibited colour photographs of the spectrum:—(1) Small spectrum, exposure about 3 minutes.—(2) Large spectrum, exposure about 6 minutes, without coloured screens. The colours seen on these plates are produced by the direct action of light; they are not due to any pigments, the substance of the films remaining colourless, but are of the same kind as the colours of soap-bubbles and mother-of-pearl, viz. interference phenomena; they are due to the structure imparted to the film by the stationary waves of incident light during exposure in the camera. These colours are perfectly permanent.

Prof. A. Schuster, F.R.S., exhibited some forms of Clark cells.

Prof. Emerson Reynolds, F.R.S., exhibited: (1) Specimens of tetrathiocarbamid-ammonium bromide, $(H_5N_2CS)_4NBr$, and related substances. (2) Series of photographs illustrating the application by Colonel Waterhouse of the above bromide to the reversal of the photographic image on gelatino-bromide of silver films.—Mr. W. Saville-Kent exhibited photographs of living corals, taken in Torres Straits.—Dr. W. Hunter exhibited a series of ptomaines—alkaloidal products formed by bacteria from animal tissues.—The Committee of the Camera Club exhibited allotropic forms of silver, prepared by Mr. Carey Lea, of Philadelphia, and described in *Amer. Journ. of Science* for 1889, and *Phil. Mag* for 1891.—Prof. G. F. Fitzgerald, F.R.S., exhibited crystals of platinum and palladium (prepared Mr. J Joly).—Prof. J. A. Ewing, F.R.S., exhibited Prof. Sekiya's model of a Japanese earthquake.—The Council of the Royal Society exhibited a cabinet containing medals struck in honour of Fellows of the Royal Society.—Mr. Edward Schunck, F.R.S., exhibited indigo-blue and allied substances and derivatives of chlorophyll.—Mr. Fred Enock exhibited microscopic preparations of the British Mymaridæ (egg parasites).—Dr. H. Woodward, F.R.S., exhibited skull and shoulder-girdle of *Procolophon trigoniceps* (Owen), collected by Dr. Exon in the Orange Free State (figured Phil. Trans., 1889, p. 267).—Mr. J. Howard Mummery exhibited specimens illustrating some points in the structure and development of dentine.—Mr. Allan Dick exhibited a new form of polarizing microscope.

Meteorological photographs, exhibited by Mr. Arthur W. Clayden. The photographs of clouds have been taken by reflection from a mirror of black glass, placed in front of the camera, so that the plane of its surface makes the polarizing angle with the axis of the lens. Those of hoar-frost show how the crystals attach themselves to the projecting portions of objects, such as the margins of leaves, the loose fibres of a string, and the thorns of a briar, and also their tendency to grow towards the direction from which the air has been moving.

THE BENUÉ AND THE KIBBÉ.

AT Monday's meeting of the Royal Geographical Society, Major Claude M. Macdonald, H.M. Commissioner to West Africa, gave an account of a journey up the Benué and its northern tributary the Kibbé, in the summer of 1889. The Benué, we need scarcely say, is the great tributary of the Niger. Major Macdonald referred to the previous explorations of Barth and others, and to the fact that it has been maintained that a connection existed between Lake Chad and the Benué, by the overflow of the Shari on one side and the Kibbé on the other. Major Macdonald has been the first to explore the Kibbé. After describing the ascent of the Benué, Major Macdonald went on to say that he and his party started on their journey up the Kibbé in the Royal Niger Company's stern-wheeler the *Benué*, on August 21.

The Kibbé at its mouth is some 250 yards wide, while the Benué is upwards of 600. The average depth of the Kibbé at this season of the year, nearly high water, is from 10 to 12 feet. On both banks for the first five miles the country is flat and well wooded, with patches of bright green grass, and looks very gamey, though owing to the high grass we saw no deer. A noticeable feature some five or six miles from the river is Mount Katie, a rounded hill, some 800 feet high, well wooded to its summit. This hill, from its isolated position, served as an excellent point on which to take angles for mapping purposes. Patches of cultivation were now to be seen on both banks, and after two hours' steaming the party passed the Fulbe village of Dinghi. The inhabitants, though they had never before seen a steamer or a white man, did not seem much disconcerted, and, when shouted to in their language, returned the salutations in a very friendly manner. On August 22 the *Benué* anchored off a large village on the left bank. "We very soon saw," Major Macdonald states, "that we had to deal with the purest-bred Fulbe we had seen so far. The crowd consisted almost entirely of women—by far the best-looking we had as yet seen on the Niger, and indeed the best-looking I have seen in either east or west Equatorial Africa. They wore the usual piece of cloth wound round their bodies, leaving their arms and shoulders bare, and reaching down below the knee. Their features, in most cases, approached the European, and their expression most gentle and modest, yet full of vivacity. They told us that the name of their village was Pamu, and that it was governed by an Emir, who was under the jurisdiction of the Emir of Yola. The men were armed with spear and bow and arrows, though they are said to be an agricultural people, and certainly it would seem so, for every yard of ground in the neighbourhood of Pamu was under cultivation. We asked them if they would bring us provisions in exchange for cloth; this they readily did, and we soon were hard at it, bartering pieces of cloth, salt, &c., for live stock, weapons, ornaments, and indeed anything. The whole time nothing but the greatest good temper prevailed, and I was much struck by their gentleness and courtesy; albeit the ladies were very good at a bargain, and I noticed that when it came to bartering their ornaments, members of the fair sex, who were not so young or so fair as their more fortunate sisters in this respect, surreptitiously handed their ornaments to the latter to dispose of, hoping thereby to get better value, and I am bound to confess they did."

Shortly after this the steamer came to a deserted strip of country, some fifteen miles in length, which was evidently the barrier between the Mahommedan and Pagan tribes; it was of an undulating character, with isolated hills, and well wooded. The river was still about 100 yards wide, but commenced to be dotted with grassy islands, and was in parts very shallow with a sandy bottom.

Next day, as the steamer advanced, the river narrowed again and made a sharp bend to the eastward, and approached a grassy range of mountains, leaving a higher range to the north. Half an hour after starting the party arrived at the foot of the grassy slopes of the former; a pathway, which could be traced for a considerable distance, wound up the face of the mountain and disappeared over one of its grassy ridges. Patches of cultivation could be seen dotted here and there; the main valley stretched back some three or four miles, but we could see no signs of a village.

"We were, however," Major Macdonald stated, "not left long in doubt as to whether the country was inhabited or not, nor as to the character of the inhabitants, for down the winding path, which was distant some 600 yards from where we were, came a line of warriors, some 200 in number; the majority of them were quite naked, though some few had a small cloth round their waists. They were all armed, mostly with spears, the almost invariable number being three. Leaving the pathway, they advanced in excellent order across the boulder-covered grassy piece of ground which lay between the river and the mountain side. We accordingly moved into mid-stream, which was only some 15 yards from the bank, and dropped anchor in about 4 feet of water. Our friends advanced straight at us, not a word being spoken, but an excellent line being maintained, when suddenly they all took cover behind boulders and tufts of grass, nothing being visible but the gleaming points of their spears. It was a source of some gratification to us that the points were gleaming, for it showed that at any rate they were not poisoned. There was now a pause. Then our Fulbe interpreter, under my directions, opened fire in a dialect of the Battawa, with satisfactory results, for they appeared to understand him. Their first question was as to whether 'we were Mahommedans? because if so we could not pass, as they were the outposts of the Pagan tribes, and had orders not to allow Mahommedans to pass.' We assured them that we were not Mahommedans. They then told us, in answer to our queries, that the name of their village was Katsho, and that it lay back from the river amongst the hills; they said that if we went on we would come to more villages. After a great deal of persuasion two of their number consented to come on board. So we sent a six-oared gig, which we had towed up with us in case of accidents, to fetch them. They were fine, well-made men, but were trembling with fright at the sight of the steamer and white men, and prostrated themselves on the deck at our feet. These two men wore loin cloths of native manufacture; the great majority of the others were, as I have said, naked. After getting as much information out of these men as we could, which information, on account of their terror and the difficulty in interpreting, was somewhat meagre, we proceeded on our way. By this time large numbers of men and boys had assembled, and ran along the banks gesticulating and pointing at our little ship. They, men and boys alike, were all armed, mostly with spears; we saw very few bows and arrows.

"The scenery now was very picturesque; to our right, *i.e.* the south of the river, some few yards from the water's edge, the mountains rose in some places quite abruptly. These mountains were for the most part covered with green wavy grass very pleasant to the eye. One or two streams trickled down the mountain side, forming now and again picturesque waterfalls. The river had suddenly broadened out to a lake, or, more properly speaking, marsh, some three miles long by two wide. The range of grassy mountains I have mentioned ran along the southern shores of the lake and terminated with it. The country on the east and north shores of the lake, as far as the eye could see in the direction of the Tuburi marsh (near the Shari river) was open and gently undulating, while from the western shores of the lake the beautiful range of mountains, with their needle-shaped peaks, stretched back apparently for many miles. In the north-east corner of the lake we saw a very large village some two miles distant; this we afterwards ascertained was Bifaré. The channel of the river evidently followed the base of the southern hills. We accordingly steamed gaily along, followed on the shore by an ever-increasing crowd, till we arrived at a large village prettily situated almost on the edge of the lake. The houses or huts were built in clusters, each cluster apparently belonging to a different family. The huts were very well constructed, having round walls some 6 feet high, with flat roofs formed by beams covered over with mud and thatch. The walls of the huts were made of black and in some places red mud, and the workmanship of both walls and roof was excellent. Several hamlets were prettily situated on the slopes of the hill, surrounded with patches of cultivation, and had the appearance of the country places of the richer inhabitants of the village.

"A large crowd had now assembled, and regarded our movements with great curiosity. We asked to see the chief of the village, and after a good deal of palaver, a man appeared attired in a very tattered 'tobe' or gown. He had something of the Fulbe in his countenance, and was a tall fine man, though of rather a forbidding appearance. He came on board, and we endeavoured to get what information we could out of him. He said the name of the big water we saw was Nabaret, but that it was only a fourth that size in the dry season. The name of his village was Kaku. The channel of the river ran along by the mountains. He knew of the Tuburi marsh, but had never been there; he did not think the river came from there as it was distant many days' journey. He knew of no other big water, but would give us a guide to show us the way. The people of the Nabaret district are possessed of cattle, but no horses; they live principally on dhurra, which they cultivate largely, and on fish which abound in the lake. They also hunt the hippopotami, of which we saw a dozen in the lake, though doubtless there may be many more.

"We took our guide on board and endeavoured to make for Bifaré, already mentioned, which appeared to be a village of quite 6000 inhabitants, situate on the north-east shores of the lake, and distant some two miles from where we were. After proceeding about 100 yards we found that the water shoaled about a foot, and even less, and though we made every effort to proceed, we were completely baffled; turning back, by direction of the guide, we went for an opening in the high dhurra, which grew in immense quantities about here, and found ourselves once more in the channel of the stream, which was, however, only some 8 yards wide and 2½ feet deep, flowing with a swift current. After proceeding with great difficulty for almost a mile, with fields of dhurra growing to a height of 8 feet on either side and completely shutting out the view, the navigation became so difficult that we had to turn back, having already smashed in the bow of our gig, bent our rudder into the shape of a bow, and more than once berthed our little ship amongst the dhurra stalks. The stream was so narrow that we could not turn, but had to float down backwards for a good half mile. The highest point reached was a mile and a half from the village of Kaku, and from what the people said, a good thirty miles from Dawa, in the Tuburi country, the furthest point reached by any European entering Africa from the north, viz. Dr. Vogel in 1854. The stream at the point where we reluctantly turned back was not more than 2 feet deep, and from 15 to 20 feet wide, and this at the period of high water. I should say that in the dry season (and this is corroborated by the natives themselves) that a man could step across it. It is more than probable, therefore, that had we been able to proceed another three miles or so, we should have arrived at its source."

It seems evident, then, from Major Macdonald's observations, that no connection can exist between the Shari and the Benué.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Mr. J. W. Clark, Superintendent of the Museum of Zoology and Comparative Anatomy, has been elected to the Office of Registrary of the University, vacant by the death of Dr. Luard.

The degree of M.A. *honoris causâ* has been conferred on Mr. J. Y. Buchanan, F.R.S., University Lecturer in Geography.

The Electors to the new Isaac Newton Studentships, founded by Mr. F. McClean, are Sir G. G. Stokes, Profs. Darwin and Thomson, Dr. Glaisher, and Mr. Glazebrook.

SOCIETIES AND ACADEMIES.

LONDON.

Zoological Society, May 5.—Prof. Flower, C.B., F.R.S., President, in the chair.—The Secretary read a report on the additions that had been made to the Society's Menagerie during the month of April 1891, and called special attention to the arrival of what appeared to be an adult male example of the Lesser Orang (*Simia morio*) of Owen, presented by Commander Ernest Rason, R.N., who had obtained it at Sarawak, and to a Great-billed Tern (*Phaethusa magnirostris*), obtained by purchase, new to the collection.—Mr. Sclater opened a discussion on the fauna of British Central Africa, by pointing out the limits of this new territory, which was computed to embrace some 54,000 square miles of land lying immediately north of the Zambezi and west of Lake Nyassa. Mr. Sclater gave an account of the principal authorities that have already written on the subject. Mr. Sclater was followed by Mr. G. A. Boulenger, who read a paper "On the State of our Knowledge of the Reptiles and Batrachians of British Central Africa." The discussion was continued by Mr. Edgar A. Smith, who read a note on the Molluscan fauna of British Central Africa; and by Mr. E. T. Newton, who communicated some general remarks on what is known of the geology of British Central Africa, stating several points to which special attention should be directed. Remarks on various branches of the same subject were made by Dr. Günther, Mr. O. Thomas, Mr. Stebbing, Mr. Slavin, and Mr. Beddard.—Mr. T. D. A. Cockerell read notes on some Slugs of the Ethiopian Region, based on specimens in the collection of the British Museum.—Dr. C. J. Forsyth-Major read a paper containing a summary of our knowledge of the extinct Mammals of the family Giraffidæ.—A communication was read from the Hon. L. W. Rothschild, F.Z.S., containing the description of a new Pigeon of the genus *Carpophaga*, from Chatham Island, South Pacific, proposed to be called *Carpophaga chathamensis*.—Colonel Beddome read descriptions of some new Land-Shells from the Indian Region.

PARIS.

Academy of Sciences, May 4.—M. Duchartre in the chair.—On the time of evaporation of water in boilers, by M. Haton de la Goupillière. The author has mathematically determined the rate of lowering of the level of the water in steam boilers of various forms.—A geometrical theorem, by M. Tarry.—On a class of ordinary linear differential equations, by M. Jules Cels.—On the convergence of recurring simple fractions, by M. H. Padé.—On an induction inclination needle, by M. H. Wild. A short note is given on some measures of magnetic inclination made with a new form of needle. It appears from the experiments that the inclination at a place can be determined within 4″·5 by a single observation. Skilled observers make the determination within 2″·5. Inclination may therefore now be determined as accurately as declination.—On a process for constructing screws suitable for the instruments to be used for the measurement of the photographic map of the heavens, by M. P. Gautier.—Quantitative studies of the chemical action of light; Part ii., reactions with different thicknesses of glass and with different forms of vessels, by M. Georges Lemoine.—On some compounds formed by mercuric chloride, by M. G. André. The methods of preparation of the subjoined compounds are given, together with analyses establishing their composition:—

(1) $4ZnCl_2, HgCl_2, 10NH_3 + 2H_2O$;
(2) $2ZnCl_2, HgCl_2, 6NH_3 + \frac{1}{2}H_2O$;
(3) $C_6H_5NHHgCl$;
(4) $C_6H_5NH_2, HgCl_2$;
(5) $5C_6H_5NHHgCl + 2HgCl_2$;
(6) $3C_6H_5NHHgCl + 2HgCl_2$;
(7) $C_6H_5.CH_2.NH_2, HgCl_2$;
(8) $C_6H_5.CH_2.NH.HgCl$.

—A general law determining, as a simple function of the chemical constitution of bodies, the temperatures of their changes of state under all pressures, by M. G. Hinrichs.—On boron selenide, by M. Paul Sabatier. The compound is prepared by the action of vapours of selenium upon amorphous boron at a red heat, or of seleniuretted hydrogen on amorphous boron at a bright red heat in a tube of Bohemian glass. The action of water upon the selenide shows it to have the same composition as the sulphide and oxide. Its formula is therefore B_2Se_3, a conclusion supported by the results of a rapid analysis.—On the action of hydriodic acid on boron bromide, by M. A. Besson. At a raised temperature the three compounds BBr_2I, $BBrI_2$, and BI_3, have been obtained.—On the basic chromites of magnesium and zinc, and the neutral chromite of cadmium, by M. G. Viard.—Preparation of disodic erythrate, by M. de Forcrand.—Discussion of the experiments of Biot on aqueous solutions of tartaric acid in presence of potash or soda, by M. G. Aignan.—Formation of dimethacrylic acid in the preparation of the acid amides of isovaleric acid, by M. E. Duvillier.—Methyl-methylcyanosuccinate, methylethenyltricarboxylic ether, by M. L. Barthe.—On the "dextrosity" of certain Gastropods called "sinisters" (Lanistes, Peraclis, Limacina, larvæ of Cymbuliidæ), by M. Paul Pelseneer.—On the structure of the composite eye of certain Crustaceæ, by M. H. Vaillanes.—Comparative structure of the inflated roots of certain umbelliferous plants, by M. Géneau de Lamarlière. It is shown that the anomaly which is observed in the inflated lateral roots of certain umbelliferous plants (Œnanthe, Carum) is more apparent than real. In plants of the same family an intermediate series should be found between the structure called normal and the structure of a normal inflated root (Daucus, Apium).—On the microscopic structure of the phosphate rocks of Dekma (Department of Constantine), by M. Bleicher. The rocks examined are said to show under the microscope the mixture of a fair proportion of osseous *débris*, whence it is thought that this is the origin of the phosphorus in rocks rich in calcium phosphate.—Note on the Quaternary strata of Éragny and Cergy (Seine-et-Oise), by M. E. Rivière.—On the production of diabetes after the destruction of the pancreas, by M. E. Hédon.—Meteorological observations on the Pamir, by M. Guillaume Capus. An account is given of thermometric observations made between March 13 and April 19, 1887, on the high plain of Pamir, the centre of the highlands of Europasia.

PYCNOGONIDS.

Den Norske Nordhavs-Expedition, 1876–78. *XX. Zoologi—Pycnogonidea.* Ved G. O. Sars. Med 15 Plancher og 1 Kart. (Christiania: Grondahl & Sons, Bogtrykkeri, 1891.)

Studies from the Biological Laboratory, Johns Hopkins University, Baltimore: A Contribution to the Embryology and Phylogeny of the Pycnogonids. By T. H. Morgan. With Eight Plates. (Baltimore: The Johns Hopkins Press, 1891.)

THE group of sea spiders, or the Pycnogonidea, was for a long time among the least known, though by no means the least interesting, of the divisions of the marine invertebrates. Linnæus described a species as a Phalangium, placing it among terrestrial forms, and though a century and a quarter has passed since then, the problem of where to place these Pycnogonids cannot be said to be finally settled.

Within the last ten years or so, an immense advance has been made in our knowledge of the morphology, anatomy, and embryology of the group, thanks to the labours of Anton Dohrn, who, in 1881, described the forms found in the Gulf of Naples, and of Hoek, who about the same date described the species found during the cruises of the *Willem Barents* and the *Challenger*. During all this period opinions varied as to whether these forms should be placed among the Arachnids or the Crustacea, but apparently both the authors just referred to have agreed that the Pycnogonids should be placed with neither, but that they, with the Arachnids and the Crustacea, have come down the stream of evolution in parallel lines.

To the existing recent memoirs of these Arthropods, the splendid volume just published on the Pycnogonidea found during the Norwegian North Atlantic Expedition, 1876–78, by Prof. G. O. Sars, adds, perhaps, from a morphological point of view, the most important of the recent publications on the group; for, valuable as beyond question are the structural and developmental details, a special knowledge of general morphological detail is also needed for the convenient understanding and classifying of any group.

The material at Prof. Sars's disposal was very large, and in addition he has made use of collections made by himself during many years back on the coasts of Norway, and also of some few forms sent to him by Dr. A. Stuxberg, which had been found in the Kara Sea during Nordenskiöld's expedition. A very great contrast is to be seen on comparing these northern forms with such a collection as that of Dohrn from the Mediterranean. The great number of species belonging to the family Nymphonidæ is specially characteristic of the Northern Seas as contrasted with the Mediterranean, while again the Northern Sea species attain very generally much larger dimensions, some being gigantic in comparison with those of the Mediterranean.

In working out the classification of the group, Sars has found it necessary to treat the families in a somewhat more restricted sense than has been done by most of the previous writers, and has been obliged to increase their number. While fully agreeing that the descriptions and even figures of the Pycnogonids given by the earlier writers leave much to be desired, and are as a rule even exceedingly defective, in some cases indeed being so bad as not to be intelligible, yet he thinks that some quite recent describers have rejected as bad a greater number of descriptions than with a little patient research was really necessary. Thus he finds it hard to believe that, while not a few species have been described from the Gulf of Naples, all the species described as found there by Dohrn, with one exception, should be new. Most certainly as regards the northern species we cannot sufficiently admire the pains which Sars has taken in working out all the imperfect descriptions and rough figures of our past recorders of new forms, with the result that he has succeeded in re-establishing many wholly forgotten or ignored species of Goodsir and others.

As regards the terminology used in describing the various parts, some, classing the Pycnogonids with the Crustacea, adopted terms in use among the latter; while others, holding their affinity to be with the Arachnids, employed again a different set of terms. Dohrn, to avoid the difficulty as regards the limbs, rejects all special terms, describing them as No. I., II., &c.; Sars uses a terminology the terms of which involve as little as possible of any homologous references.

Forty-three species are described and figured. Several of them are here fully described for the first time, though short diagnoses of them appeared in a preliminary report. The fourteen genera are arranged in eight families, and these are grouped into three orders, the ordinal characters being based on the relations of the "chelifors." Thus in Order 1, Achelata, these chelæ are, except in the larval state, entirely absent; in Order 2, Euchelata, the chelæ are well developed throughout all the stages of life; while in Order 3, Cryptochela, the chelæ are present, as a rule, in the young stages (not alone in the larvæ), but in the fully developed condition they become atrophied or disappear. This arrangement no doubt will have to be modified so as to fit it to receive the very numerous forms from other parts of the world, but it is a first step in the right direction of an intelligent grouping of the genera.

The second memoir on our list treats of the Pycnogonids from a different standpoint, being a contribution to our knowledge of the embryology and phylogeny of the group, by T. H. Morgan, Fellow of Johns Hopkins University. After a short allusion to the work of Dohrn and Hoek, who have "placed the morphology of the order on a very firm basis," he proceeds to treat of the early stages of the embryology of the Pycnogonids, stages which have been practically unexamined, and a knowledge of which is needed to enable the relationship of the group to be guessed at.

The material for this work was collected at Wood's Holl. Three genera, each with a single species, are to be found at this place—*Pallene empusa*, *Phoxichilidium maxillare*, and *Tanystylum orbiculare;* and during July, August, and September, these were found carrying ova. The alcoholic picro-sulphuric acid process was adopted for hardening; the eggs being cut in paraffin. The eggs of Pallene were large, 0·25 mm., and well adapted for investigation. After a minute description of the early stages of development, the author considers that from them there is little or no ground for a comparison between the Pycnogonids and the Crustacea, certainly not with any existing forms. The multipolar delamination of the endoderm in the Pycnogonids has no homologue amongst the Crustacea, nor is there any special similarity in the formations of the organs. There seems to be no trace of gastrulation like that in the Crustacean in the ontogeny of the group. And if there be reason for rejecting a relationship between the Pantopod larva and the Nauplius, and with Dohrn he believes that there is, then there remains nothing in common to the ontogeny of the two groups.

Nor are there any special affinities between the insects and Pycnogonids; but between these latter and Peripatus a striking similarity is met with in the paired ventral organs, both in the structure and position of these, but for the present there is no proof forthcoming as to a real homology of these bodies. The process of the formation of the endoderm, as described by Heider and by Wheeler in insects, shows a certain resemblance to multipolar delamination; but if it be such, it is a more complicated form than is shown by the Pycnogonids. With these two exceptions there would seem to be nothing else in common in the ontogeny of the two groups.

Lastly, as to a decision as to the relationship with the Arachnids, or as to their being an independent phylum. While Dohrn and Hoek ably maintain the latter, though not agreeing as to the why in all details, yet the study of the early stages of the embryology has brought to light certain facts which lead the author of this memoir to believe in a community of descent between the two. The reasons for this belief are given in full detail, with difficulty admitting of abbreviation. The Pycnogonids form the endoderm by a process of multipolar delamination, which is shown in its simplest form in Phoxichilidium and Tanystylum, and in a more modified condition in Pallene. In no other group of the Triploblastica is a similar phenomenon found except in the Arachnids. In the spiders the process is not so well marked, but if Balfour's conception of the formation of the yolk nuclei be correct, then a direct comparison may be made between the two groups. The first trace of the embryo to appear in Pallene is a round opaque area at the spot where the stomodæum invaginates. In Schimkewitsch's recent account of the development of the spiders, he shows that the primitive cumulus in them is the place where the stomodæum invaginates; and in calling attention to the fact that the stomodæum of spiders in its earliest development is a triangular invagination, he actually compares it with the triangular invagination of the œsophagus of the Pycnogonids. It is also exceedingly probable that the early formation of the body cavity surrounded by mesoblast in the legs of spiders has an exact parallel in Pallene and Phoxichilidium. In both Arachnids and Pycnogonids there are well-marked diverticula from the mid gut into the legs. In both Arachnids and Pycnogonids the first pair of appendages are chelate, and in both this first pair is innervated from the brain; these facts alone, it will be remembered, were considered by Balfour to indicate a relationship between the groups. Mr. Morgan was unable to find any post-oral ganglia for Pallene, but the first pair of appendages arises on the sides of the stomodæum and moves forward later. In this respect, it compares closely with the spiders, and the early innervation of this pair from the brain itself may be regarded as a more abbreviated condition than what was seen (by Balfour) in the spiders. Metchnikoff's figures for Chelifer show the first pair of appendages to arise above and on each side of the proboscis-like upper lip, and if future investigation verifies Metchnikoff's suggestion that this proboscis is homologous, entirely or in part, to the proboscis of the Pycnogonids, as his figure seems to indicate, then does the whole development of the Chelifer show remarkably close resemblances to that of the Pycnogonids. The fourth pair of ambulatory legs—the seventh pair of appendages—has been a stumbling-block in the way of an Arachnid relationship, and the attempts to solve the difficulty have been many. Here, again, Balfour's suggestion that this last segment and its appendages may represent the first abdominal segment of the Arachnids is of value, as we know that the embryos of spiders have rudimentary appendages on the abdomen. In a second part of this memoir the metamorphosis of Tanystylum is described, and in a third part we have a very complete study of the structure and development of the eyes of Pycnogonids and a comparison with the Arachnid simple eyes, a comparison that seems to verify the relationship pointed out in the first part of the memoir. E. P. W.

A TEXT-BOOK OF CHEMISTRY BASED ON THE PERIODIC SYSTEM.

A System of Inorganic Chemistry. By William Ramsay, Ph.D., F.R.S. Pp. 700. (London: J. and A. Churchill, 1891.)

During the twenty-five years or so which have elapsed since the recognition of the periodic law of the chemical elements as a valid relationship, the pronounced influence which it has exercised both on the aspect and aims of chemical science cannot be questioned. Whether in the prediction of undiscovered elements, or as an indicator of needful research, especially in the department of atomic weight estimations, it has met with signal success. In connecting the physical properties of the elements themselves and of their compounds with atomic weight, it has opened up new fields of investigation, and thrown fresh interest into old ones. Properties so widely different as those measured by refraction equivalent and breaking stress find an explanation, nowadays, in the magnitudes of the atomic weights.

As a means of classification, too, the success of the periodic arrangement has not been less striking. Indeed, to its power as an instrument of classification it owes its general acceptance in the first instance. When the ideas of Avogadro had become recognized, and by their means the old system of "equivalents" had been replaced by the true atomic weights, then the periodic arrangement resulted in a grouping of the elements so much in harmony with existing notions of their relationships, that the far-reaching power of the generalization could no longer be resisted.

The distinguishing feature of the book before us consists in the use of the periodic arrangement as a means of classifying the subject-matter of inorganic chemistry. Here, the time-honoured methods of putting the facts and theories of chemistry before the student are set aside, and as the method adopted is novel to English text-books, it may be advisable to consider its characteristics. After a short historical introduction, the author proceeds to describe the occurrence, preparation, and properties of the elements in the order in which they are found in the periodic table. First, Group I., hydrogen and the alkali metals; then Group II., metals of the alkaline earths, and so forth. The descriptions refer, as far as possible, to the elements of the same group taken collectively.

The compounds of elements of the different groups with the halogens form the next part, and in the introductory portion the student meets for the first time with matter which it is customary to discuss at an earlier stage in the text-books; such matter as the distinction between element and compound, the use of chemical symbols, the gaseous laws, &c. The fourth part deals with the oxides, sulphides, selenides, and tellurides, and under these headings are to be found hydroxides, hydrosulphides, &c., classed as compounds of the oxides with water, hydrogen sulphide, &c. Here, also, are treated the salts of the oxyacids, classed as double oxides, and compounds as $POCl_3$ treated as double compounds with the halogens.

Part v. gives an account of the borides, carbides, and silicides; such of the hydrocarbons as are considered, and the organo-metallic compounds occur in this part. Compounds with the elements of the nitrogen group, including the cyanides, form Part vi. Alloys and amalgams are discussed in Part vii. The first chapter of the next part gives a short account of spectrum analysis and the rare earths. The second chapter is chiefly concerned with the criteria for fixing atomic and molecular weights, the Raoult methods finding a place, and the last chapter is devoted to the periodic law. The closing part of the book takes up, mainly with regard to the chemical principles involved, the manufacturing processes usually treated in the text-books.

It will be seen, as the author states in his preface, that the method adopted does away with the distinction between metals and non-metals; no special stress is laid on the properties of acids as contrasted with bases; equal prominence is given to rare and more common substances; and the commercial importance of a substance or process is not considered an argument for its special consideration.

Such a work as this may be looked at from two points of view. Regarded as a systematic arrangement of the facts of inorganic chemistry, from which any desired information may be speedily taken after one has become familiarized with the method of classification adopted, its success is undoubted. The book is quite in touch with recent investigations, nothing of importance seems to be omitted from the descriptive portion, and, what is a recommendation to a large class of readers, the size of the book is not excessive. Whatever be the results of the system adopted, economy of space is assuredly achieved. To the teacher or to the advanced student who wishes to use the book as a work of reference, or desires to systematize his knowledge, it will be eminently useful.

If, on the other hand, the system be regarded from the point of view of a basis for teaching, its construction from its very novelty must be open to discussion. A method of teaching chemistry often employed may be said to consist in giving the learner in as easy a manner as possible the leading facts of chemical science with regard, in the first instance, more to the correct appreciation of the meaning of the facts themselves, than of the exact arrangement or classification of the same. To this end the student is led from the study of the chemical properties of commonly occurring bodies to the description of the elements contained in them, explanations of chemical terms being given as they crop up, or in short reviews at intervals not far apart. When the properties of the elements are being explained, their reactions with other elements have to be noticed, and hence it appears natural to describe the important compounds of an element after its own properties have been discussed. The periodic system does not seem to provide the means for such a course of teaching, and this appears to us to be the main reason for its non-adoption in the text-books.

Indeed, the new method has little in common with that indicated above. The entire series of the elements apart from their compounds are described, and chemical and physical terms are freely used without any attempt being made to define them till all the elements have been treated. In fact, a few terms, as critical point and heat of formation, are used, but as far as we can see, not defined in the book. Again, compounds containing a common constituent are classed together, but compounds of what may be taken as a parent element are scattered throughout the various groups. Surely, in connection with this point, reasons similar to those which lead to the grouping of compounds containing the same element, on the new system, would hold for the old method of considering compounds. The position of the iron group of elements after the aluminium group and of the copper group—the last one described—may be taken as an indication that even in the author's opinion the periodic law does not in all cases indicate most clearly the relationships of the elements. Such considerations as these must weigh with a teacher before he can adopt the system; during four years' experience, however, the author has had no reason to doubt its success.

The book is clearly printed, and the illustrations, though not very numerous, are for the most part new. The frequent use of vapour jackets in the apparatus represented is suggestive of the author's more recent contributions to scientific literature. The useful system adopted by Ostwald in his "Lehrbuch," of indicating the state of aggregation of a substance by the type, has been employed.

Setting aside the points which may be urged against the work as a basis for teaching, the periodic law, as expounded by Prof. Ramsay, does more than any other system of classification to put the matter of inorganic chemistry on a footing resembling that which holds for organic chemistry.

OUR BOOK SHELF.

Eighteen Years of University Extension. By R. D. Roberts, M.A., D.Sc. (Lond.). (Cambridge: University Press, 1891.)

THE University Extension movement takes so prominent a place among the educational influences of the age that a good account of the system has for some time been needed. This is supplied by Mr. Roberts, who, first as lecturer, then since 1881 as assistant and organizing secretary to the Cambridge Syndicate, and since 1886 as secretary to the London Society, has had the best possible opportunities of studying the new method, and of forming a judgment as to its fitness for the uses to which it is applied. He begins with an account of the origin and growth of the movement, then describes the character of the audiences, the reception of the idea by artisans, and the signs of earnestness displayed by various classes of students. Mr. Roberts also discusses the conditions of success, has a chapter on the consolidation of the work, and presents a summary of results. No essential fact has been omitted, and the general impression which will be left on the minds of most readers probably is that those connected with the movement have done much to foster and to satisfy the desire of a very large number of persons for intellectual training. There are certain rules—some of them rather difficult—with which the system must be brought into accord if it is to be capable of further development; and these are stated with much force and precision in the present useful little volume.

Evening Work for Amateur Photographers. By T. C. Hepworth, F.C.S. (London: Hazell, Watson, and Viney, Ltd., 1890.)

IN this book the author has written, in an interesting manner, a series of chapters relating to many points in photography that are generally found most useful to amateurs. The following are the subjects of some of the chapters: lantern entertainments, lantern-slides on gelatine plates, clouds in lantern pictures, frame-making, enlarging, photography by magnesium light. There are also two or three chapters on electric light, light by incandescence, and methods of making cheap batteries.

The subjects are treated in a manner that makes the book well worth reading, and its value is increased by numerous illustrations obtained from photographs and drawings by the author.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The University of London Question.

THE Convocation of the University of London has, by a large majority, thrown out the scheme for the reconstitution of the University proposed by the Senate. Even those who had little love for it must feel some sympathy at the frustration of labours which were as patient as they were undoubtedly disinterested.

For the moment the whole question remains in abeyance. I am disposed to think that it may be useful to discuss, in the interval which must elapse before any further step is taken, some of the fundamental questions which seem to me to underlie the solution of the problem, and have never, as it seems to me, been properly considered.

On such a subject one might easily write a great deal. For the sake of brevity I shall therefore attempt to sum up what I have to say under separate heads.

The Examination System.

One factor in the present situation is undoubtedly the growing dissatisfaction of many distinguished teachers with the examination system as applied to University education. And as the University of London at present does nothing but examine, it is obvious that the question lies at the root of any judgment that may be pronounced on its present work and constitution. Those who wish to know all that can be said against the present use of examinations in University work cannot do better than study a paper by Prof. Lankester, which he has reprinted in his "Advancement of Science" (pp. 175–192). He has stated his case with all the force and lucidity of which he is a happy master. He sees "the most injurious result of the system" in "the degradation of the teacher." The "intrusive board of examiners" draws "away from him the attention and the respect of his pupils," or urges "him to put aside his own thought and experience, and to teach the conventional and commonplace."

I am free to admit that there is a certain element of truth in what Prof. Lankester says. But having had, like him, a good deal of experience both of examining and of being examined, I am disposed to think the picture somewhat over-coloured. No doubt the University of London in the past has exalted examination into a sort of idol. But as regards the superior degrees in science and medicine, at any rate, examination is now practically dispensed with, and the test of competence is the performance of some kind of original investigation.

For the inferior degrees, as far as I am aware, the examination system in more or less prescribed subjects obtains everywhere in the three kingdoms. For my part, I think the system may be defended, and upon the same lines as those on which Prof. Lankester defends "leaving examinations" at schools. For he says, and I think rightly, that such an examination "may be regarded as a means of criticizing and testing the performance not merely of the schoolboys but of the schoolmasters." Now in University education, as carried on in this country, I can only see a prolongation of school education, with methods and a moral discipline modified to suit the more advanced age of the pupils. And the inferior degree (I am not speaking, of course, of professional subjects) is, in my view, nothing more than the corresponding "leaving examination." It is a test of whether teaching has been faithfully done and learning diligently pursued.

I am quite ready to admit that impending examinations are more or less irksome both to teachers and taught; but I am not convinced that that discipline is in itself an evil. It is not undesirable that some restraint should be put on the possible vagaries of the one and the very probable desultoriness of the other. It is necessary in entering upon the study of a subject to go over its fundamental groundwork in a methodical manner. To many teachers and to many pupils this is not a little dull. It is easy and it is pleasant to dwell at some length on attractive parts of a subject and to skim superficially over others. There are probably few persons who, looking back upon their own student days, will not admit the truth of this. The fact is that to get any mastery of a subject one must learn its grammar; and the majority of young people require some degree of compulsion to make them do it. It may be irksome at the time, but the advantage is life-long. I know, speaking from my own experience, that the compulsion of schedules which is so odious to Prof. Lankester has made me devote my energies to the mastery of the rudiments at any rate of many subjects which I should certainly have carefully avoided if I had not been compelled to do otherwise. And I do not believe that, if students are carefully and soundly taught, they suffer any real injustice at the hands of competent examiners. But then I agree with Prof. Lankester that the examiners must know their business, and must not be either ill-informed or pedantic. No one, I think, can urge that the kind of men that the University of London enlists in its service as examiners are open to the charge of being either.

If these views are correct, and I believe in the main they are, then the evil consists not in the examination system as the incentive to the orderly performance of a curriculum, but in another and perfectly distinct evil on which Prof. Lankester very sagaciously puts his finger—the mischievous importance which the outside world attaches to academic achievement. "A man refers throughout his life to the fact that he obtained a 'first-class' as a sort of perpetual testimonial." Of course, in so far as this is true it is very absurd. A course of University study is a means, not an end; it is a sort of apprenticeship to a subject. The student learns its technique, its language, and something of its literature. If he has done this earnestly and well, his University will applaud him, will call him in academic language "a good boy." But when the congratulation of his friends has subsided, the real question arises, what will he do with the tools he has learnt to use? Here, I think, University work enters upon a new phase, and one, it seems to me, too little regarded—I mean post-graduate study. To control this in any measure by means of examination seems to me in the highest degree absurd. And I must contend that by making original investigation, at any rate for its doctorate of science, the qualification for that degree, the University of London has taken a step in advance of many of the older Universities towards destroying the idea that the passing of examinations is the final end of University study.

A Teaching University.

I have always found it not a little difficult to understand what those people exactly mean who so strenuously demand a teaching University for London. What Prof. Lankester means, there can, as is usually the case, be no sort of doubt about; and this I shall discuss presently. But, as far as I can make out, all other persons seem to think that London University students labour under some special disadvantage which undergraduates at Oxford and Cambridge do not experience. Perhaps, then, it may surprise many to be told that there is no essential difference in the two cases. Examining in the two older Universities is in the hands of the University, and is just as much distinct from the teaching in their case as in that of London. I can speak with some positiveness upon this point, for having been for four years an examiner for the Natural Science Tripos at Cambridge, a University with which I have no connection, I found the functions I was called upon to perform exactly the same as those I have also fulfilled at Burlington Gardens. In fact, I can see no essential difference between the position of an undergraduate of New College, Oxford, examined for his degree by the local University and an undergraduate of University College, London, examined by the University of the capital. If Oxford and Cambridge are teaching Universities in any intelligible sense of the phrase, then I contend that the University of London is equally so.

Prof. Lankester adopts the view of Fichte, who says "that a University is not a place where instruction is given, but an institution for the training of experts in the art of making knowledge, and that this end is attained by the association of the pupil with his professor in the inquiries which the latter initiates and pursues." Most excellent, and I can imagine nothing more delightful than for some wealthy man to give, say, half a million of money to found such a University in some quiet country town in England, where professor and pupils might labour together, undisturbed by the life and movement of a big city, or the worry of the examination-room, for the advancement of knowledge But if such "a seat of learning," in the true sense of the words, could be brought into existence, it would probably be found in practice that the students would be men who had already graduated, *i.e.* in my view acquired that knowledge of the elements of a subject which is essential to the proper performance of any work in it. A Professor of Biology, for example, would not care to have to teach a pupil at the commencement of a research how to interpret what he saw through the microscope, or how to cut a section. And if we firmly grasp the idea of the non-finality of the graduation course, we get an intelligible distribution of labour amongst the staffs of the older Universities: the college lecturers will prepare men for their degrees; the professors will guide their maturer studies afterwards.

While I cannot help thinking that those who advocate the creation of a so-called teaching University in London, have got hold of an idea which they have only imperfectly assimilated, it is still worth while to examine some of the ways in which it might be realized.

With an adequate endowment a new so-called teaching University might no doubt be established in London. It would have a staff of professors who, we may assume, would be adequately paid. The posts would in that case be no doubt filled with men of distinction and eminence. Would they be able to spend their time, full of enthusiam but free from care, in leading students in the paths of research after Prof. Lankester's ideal? Not a bit of it. Such an institution would not be very different from a Scotch University, where one of the most distinguished scholars of his age is said to have found his time largely taken up with teaching schoolboys of larger growth the mysteries of Greek irregular verbs. In proportion as the new institution became a success the drudgery would increase and the advantage diminish. The bigger a professor's class the less personal contact he can have with his pupils, till at last he has to rely for any influence at all on the stimulus of lecture-room oratory. As Mrs. Garrett-Anderson has, it seems to me, correctly pointed out in the *Times*, there is very little really to be said in favour of anything like a great central teaching institution for such a city as London.

The other alternative is to combine University and King's Colleges into a teaching University. But can this be regarded as in any way a statesman-like proposal? Why should two out of many institutions be picked out for University honours? And can anyone really suppose that such a settlement would have any finality about it? Why, for example, should Bedford College be left out, developing, as it apparently is, in usefulness and activity every day? Then how can the Royal College of Science at South Kensington be ignored? It is already in popular esteem ranked as a University, and bids fair to become in time in actual fact the great science University of the country. Why, too, ignore the City and Guilds Institute? It is difficult, then, to believe that a teaching University founded on University and King's Colleges can be regarded as in any way a final solution of the problem. If it is sought in this direction it must be based on a wider federation of institutions of academic rank. But in this case all the teachers will have something to say as to the conditions of common examination. Yet, according to Prof. Lankester, the essence of a true teaching University idea is the "absence of examiners—the professor himself is examiner and teacher in one." Schedules will nevertheless reproduce themselves, and the influence of colleagues will be quite as much an obstacle to the independence of the individual professor as the oppression of boards of examiners.

Furthermore, it is quite a mistake to suppose that unless the existing University is abolished, it will be possible for a younger one to escape its influence. Notwithstanding the establishment of the Victoria University, it is still found necessary, and at the request of Owens College, to hold the examinations of the University of London in Manchester. Consequently, the professors of Owens College have to adapt their teaching to a double curriculum. If the proposed University of Westminster were founded, it cannot be doubted that the same thing would happen. The professors would still have to bow their necks to the yoke of the Burlington Gardens schedules.

Expansion of Existing University.

It may be taken as quite certain that the existing University of London is too well rooted in the esteem of the community to be got rid of. Nor, with its own consent, will it readily submit to be mutilated or dismembered. And its pride and confidence in itself admits of easy justification. With all its demerits it can hardly be denied that it has accomplished a great work in raising the standard, throughout the country, of academic education. This need not be wondered at, seeing that it has always succeeded in enlisting in its service the most accomplished and distinguished men in every branch of education. If examination is to be conducted at all, I can hardly imagine conditions more favourable to its conduct than the University of London affords.

Instead of trying to diminish and curtail the usefulness of an institution which has such strong claims on public gratitude, I prefer to make the suggestion—and it is odd that it should have any novelty about it—that the future needs of University education in London should be provided for by an expansion of the existing University. This has always been the ambition of Convocation, and many, I know, share my own opinion that, if the Senate would have given greater heed to the representations which the former body has from time to time made to it, the present crisis in the history of the University would never have arisen.

I will briefly indicate the by no means drastic changes by which this might be gradually provided for.

Organization of the Faculties.

I am myself personally impressed with the conviction that the first step that should be taken in the interests of the higher education in London, and of those parts of the country which look to London for academic guidance, is the organization of the faculties. Everyone is agreed, whatever view they take on the examination question, that the teaching bodies should be brought into as intimate a relation as possible with the central University. At present there is no recognized channel of communication between them, and it has been long felt that this is a great evil. Examination is an art, and it is a progressive art. To minimize its possible harmfulness it should keep touch with the teaching. And it must be admitted that the system which now obtains at the University of London does not make this always easy. The Senate is hard to move and slow to act. This would not be so if those who had the right to move it possessed the momentum which would be derived from a more obvious authority. In fact this tendency to inaction arises from a natural timidity. The Senate is too largely composed of persons who have no direct touch with actual education.

The momentum to which I have referred above would come with all needful force from the faculties if they were organized in a comprehensive way to include every competent authority in academic education in London. I will not stop to discuss the precise machinery by which this should be brought about. It seems to me that it would be probably sufficient if the Senate were to have power to admit to the faculties the teachers of all institutions of academic rank which supplied it with candidates. To these should be added the past and present examiners, a certain number of non-graduates conspicuous for their distinction in the subjects with which the faculty was occupied, and a proper proportion of members of Convocation.

Such a body would occupy itself with any and every subject relating to academic education. Its resolutions would embody the deliberate conviction of instructed and competent persons, and would afford the Senate a solid basis for administrative procedure. I need hardly say that the faculties—if they took, as I doubt not they would do, a just view of their functions—would look to the advance of academic interests as a whole; they would not seek the sole advantage of the central University, but would watch and work for the interests of the collegiate institutions they represented—whether in London or the provinces—as well.

Boards of Studies.

Delegations from the faculties should be intrusted with the duty of watching the examination work and advising the Senate thereupon. This they would do in two ways: (1) they would consider from time to time all alterations necessary in the schedules so as to keep the examinations as closely as possible in touch with the best teaching; (2) they would review the conduct of the examinations, though without in any way interfering with the examiners. It would be their duty to consider the papers set, and criticize them if necessary, and they would consider and report on any apparent variation in the standard as evidenced by any sudden change in the percentage of passes and rejections.

Reform of the Senate.

I think it is generally admitted that the time has come when some change in the constitution of the Senate is advisable. At present it is an assembly of notables appointed for life. Many of them never attend, and some, appointed apparently on purely political grounds—and these are not always the least competent—never perhaps have attended. On the whole, the Senate, though individually eminent, is, it must be confessed, ill-informed on educational matters. As I have already hinted, it is apt in consequence to be somewhat timid and irresolute when it ought to act with decision; it is equally apt, I am afraid, to act with precipitancy when it ultimately realizes the necessity of moving at all.

The Senate must, however, remain the supreme governing body with whom the final decision must always remain in matters of importance. This being so, it seems not too much to ask that it should be an efficiently constituted body, and that the members should attend to their duties. Tenure of office for life it would seem desirable to abolish, and prolonged absence from attendance, say for a year, should *ipso facto* vacate a seat. As for the Crown nominees, who are in great part statesmen of high rank, it would be on obvious grounds unwise to dispense with them, if they took, as many of them do, sufficient interest in the work to attend with some regularity. Where the Senate needs strengthening is in experts in academic education; and it appears to me that the faculties, if constituted as above, might be intrusted with the duty of selecting these members of the Senate from their own ranks. On the whole, it might be convenient to constitute the Senate something on the lines of the Hebdomadal Council at Oxford: a third to be appointed by the Crown, a third to be appointed by the faculties, and a third by Convocation.

Higher Teaching.

There is still, however, one direction in which the University of London might even more closely associate itself with actual teaching, and so far become in actual fact a teaching University. This was pointed out in 1872 by the late Registrar, Dr. Carpenter, in his evidence before the Royal Commission on Scientific Instruction. He said (Minutes of Evidence, 10,925), "I think it very important that the State should provide for the carrying on of those higher researches, and that higher teaching, which are not provided for in any shape at present." Again (10,926), "I think that a body like the University of London might very advantageously be empowered to take up such higher and more special teaching. At present the University of London has nothing to do with teaching. The principle of the University is to recognize existing institutions. I do not think that it would be at all the function of the University to interfere or compete in any way with the institutions which it recognizes. But I should myself be very glad to see the University empowered to carry out courses of instruction of a higher and more special kind than are given in any of the institutions affiliated to it." The scope of this higher teaching was brought out more clearly in a subsequent part of Dr. Carpenter's evidence in answer to a question of Prof. Henry Smith's (10,953). He asked, "The Senate might at some future time endeavour, might they not, to have such lectures given in connection with the University of London as are now given in the Collège de France?—Yes, more of that character."

Such lectures would serve for the post-graduate study, provision for which seems to me the great defect in University education as it exists in London. And the professorships themselves would be positions which could be filled by eminent scientific men whom it is difficult as things are to retain in the capital. To take biological subjects as an example, the continual draining away of men like Michael Foster, Burdon Sanderson, and Lankester seems to me a real loss to the intellectual life of London.

It is just possible that it may be objected that the proposal to have a superior professoriate attached to the University is in some degree a slight on the Colleges and their teachers. And it may be urged that, if there were any demand for post-graduate teaching, the Colleges are quite competent to provide it. It may be so; but in practice I do not believe it feasible. The working day is inelastic, and from what I myself know of the labour involved in what may be called systematic graduation courses, I do not believe that the same man can superadd the higher work as well. Besides, to be of any value, it must not be formal and perfunctory; the essence of the higher teaching is that it should reflect the research to which the occupant of each chair should be able to devote the whole of his time.

I do not think that such professorships will be founded as long as the University is under the control of the State. For this and other reasons I should gladly see the University cease to be a quasi-Government institution, and launch out on its own resources. It seems almost incredible, but it is a fact, that at the present time not the slightest alteration can be made in a schedule without the approval of the Home Office, or the slightest alteration in the amount of prizes without that of the Treasury. There is no inducement now to the public to provide endowments, because, as the University nearly pays its way, any public benefaction would only tend to create a surplus, which would have to be paid over to the Exchequer. But I can hardly doubt that if the University were cut adrift from the State it would receive endowments which would enable it from time to time to found useful and important chairs. These would form not an unwelcome addition to the too few prizes accessible to those who devote themselves to learning for its own sake.

I had it in my mind to say a few words about the very complicated but independent problem which medical University education in London presents. But this paper has already run to an intolerable length, and the subject is perhaps of limited interest to the readers of NATURE. But I may say that I believe that the organization of a strong medical faculty would bring about the solution of all existing difficulties.

W. T. THISELTON DYER.

Royal Gardens, Kew, May 18.

A NOTE in the last issue of NATURE (p. 39) seems to assume that the present University of London is nothing but an Imperial Examining Board that has got wrongly named, and stands in the way of London possessing the educational advantages of a German University town.

I venture to offer some facts and considerations which may modify this view, and perhaps aid in forming a juster conception of the real nature of the University question than is commonly entertained.

Much more important matters are involved in the question than the maintenance or extension of existing institutions, though these are quite legitimate subjects of discussion and defence; and in the columns of NATURE it is only upon the broad ground of the advancement of science and learning that the question can be dealt with.

The epithet "Imperial" is intended to imply some unfitness on the part of the present University for other than "Imperial" functions, whatever these may be. But the University has not, and never has had, the least claim to any such title. It has never at any time held colonial examinations of its own motion. It has never at any time held any colonial examinations whatever in the faculty of science, or in the faculty of medicine, or for honours in any faculty, or for any of the higher degrees. What examinations it holds in any colony are held only at the request of the Governor of the colony, transmitted through the Colonial Office, and are practically confined to matriculation and the intermediate examination in arts. Occasionally, but very rarely, an examination in laws or for the Bachelor of Arts is held in some colony. In 1890, 16 candidates matriculated in the colonies, and 5 passed the intermediate examination in arts out of a total of some 5000 candidates. Not a single degree examination was held in any colony. In fact, these colonial examinations, which, few as they are, yearly diminish in number, never formed part of the University scheme. They were instituted about 1864 at the request of the colony of Mauritius, but were extended and have been maintained chiefly to facilitate the award of the scholarships at the disposal of the Gilchrist Trustees. Not only is the University of London not an Imperial University, but it is even less British in character than probably either of the older Universities. Very few of its candidates come from Scotland, fewer still from Ireland, and my strong impression is that the great majority come from midland and southern England. I should not be surprised even to find that a considerable majority are now drawn from an area having London for its centre with a radius of not more than 100 miles. The probable establishment, at no very remote period, of provincial Universities will practically give a still more exclusive sense to the name University of London.

It may next be asked what precisely is meant by a "teaching University in and for London," the creation of which is constantly put forward as the principal educational need of the metropolis. Is the proposed University to be "for" London in some sense in which the University of Oxford is not "for" Oxford, or that of Edinburgh not "for" Edinburgh? I know of no University, British or German, which is "for" the particular town or district in which it has its local habitation. Or is the proposed University to be "for" London in some sense in which the existing University is not "for" London as well as the rest of the country? The words seem mere surplusage, unless intended to impose local limitations which no University has ever yet imposed upon itself.

The expression "teaching University," too, stands in need of exacter definition. The University of Edinburgh is a teaching University, so is that of Dublin, so are the German Universities. Oxford and Cambridge are only in part teaching Universities; the greater part of the teaching is done by the Colleges. The Victoria University is not, in fact, a teaching University at all; the teaching is the work of its Colleges, and the proposed "teaching University in and for London" would, as far as actual teaching is concerned, resemble the Victoria University rather than a Scotch or German University. At this point the *crux* of the whole question reveals itself. The really distinguishing feature of the new University as contrasted with the University of London would be the examination of collegiate candidates (and those only) by their teachers in alleged conformity with the principle that examination should follow teaching. But it may be admitted that teaching ought to be adapted to examination, or examination to teaching, without admitting any advantage in the system of teachers settling the examination of their own students, collegiate or not. The combined teacher-examiner system is not wholly trusted by its supporters. At the older Universities the examiners are by no means usually the teachers of the candidates; at the Victoria University one of the examiners is always an "external" one. I am not quite sure how the matter stands at the Scotch and Irish Universities. To assert that such partial or semi-partial modes of testing knowledge are superior to disinterested and independent methods is merely to make an assumption, announce an opinion. What comparison of the working of both systems proves any superiority on the part of the first-mentioned of them? Do the pass degrees of Scotch or Irish Universities, or even of Oxford or Cambridge, stand higher than those of London?

Further, is it not misleading to characterize the University of London as a mere Examining Board? Of the three functions of such a teaching University as that of Edinburgh, it performs two. It directs teaching by syllabuses and regulations (prepared with extreme care, and not without ample reference to the best authorities on all matters of special knowledge), and it tests teaching by absolutely impartial and disinterested examinations, but it does not—without space, funds, and appliances it could not—pretend to teach. Nothing, however, in its nature or essence forbids its development, alone or in union or conjunction with other institutions, into what would be an ideal University of the non-residential order, neither coercive nor exclusive—one that should offer proper University instruction to all comers, and, at the same time, confer degrees upon open examinations independently (save for obvious reasons in relation to medical degrees) of place or mode of instruction.

The part the existing University of London has played in the advancement of learning may be indicated by the fact mentioned by the Vice-Chancellor in his Presentation speech, that during the last thirty years—that is, since its examinations were thrown open—the number of degrees conferred by the University has increased tenfold. This, however, is only one of the ways in which its influence is shown; the great advance in scientific education the last fifty years have witnessed is almost wholly due to the stimulus and example of the University of London. But the subject is too large a one to be dealt with on the present occasion, and indeed, from its nature, scarcely lends itself to treatment capable of doing full justice to the University.

The work of a University should not be confined to the education of graduates. Its crowning function is the exposition and illustration of the higher learning along the whole line of advance. Such is the task so admirably accomplished by the Sorbonne and the Collège de France, and to the world of science and learning in London the University of London is peculiarly well adapted, by its independence and impartiality, to render similar services. Some years ago an attempt was made to work out a scheme having this end in view, but, in deference to reasons that no longer exist, it was found necessary to abandon its further prosecution. Its resumption has now become, or may shortly become, simply a question of means, and the time is at hand when a strong effort ought to be made to afford scholars and men of science in London some of the advantages their brethren have so long enjoyed in Paris.

Richmond, May 19. F. VICTOR DICKINS.

Co-adaptation.

WRITTEN letters remain. It is for anyone who may read this correspondence through at one time to judge on which side lie the "valid" distinctions, and on which the "invalid" confusions—not to mention comparisons in respect of "verbiage" or mere personalities. But I am obliged to write once more to insist, for the fourth time, that my agreement with Prof. Meldola does *not* extend to the "conclusion as to the non-existence of co-adaptation," but only to stating that co adaptation must be proved not to exist, if "Mr. Spencer's argument" is to be logically met. And if, as Prof. Meldola now says, any such statement is to be found in his "review of Mr. Pascoe's book" (which, I repeat, merely reproduces "Mr. Wallace's argument" as to the *accumulation* of *adaptations*, without remarking that this has no relevancy to the argument from *co-adaptation*), it must be in that "language of their own" which the neo-Darwinians find "to be intelligible among themselves."

Christ Church, Oxford, May 15. GEORGE J. ROMANES.

A priori Reasoning.

I SEEM to have failed to make my contention clear to Mr. Cockerell, and will try once more. What I maintain is this:

that it is unscientific—unphilosophical—to state an hypothesis or formulate a theory, and much more so to make a categorical statement, when no antecedent facts are given nor any subsequent verification attempted. Thus, Mr. Cockerell asks the question, "Why is it that plants growing on exposed sea-shores have a tendency to lie upon the ground or otherwise *to evade the violence of the winds*" (my italics)? Now, what evidence has he to bring forward that the *purpose* of lying down is to evade the violence of the winds? So far, it is nothing more than his private opinion—an *a priori* assumption. It is true that he adds a reason, but it is also drawn from his own consciousness, and not from nature: "When a plant is growing among others, it has to compete with them in raising itself into conspicuousness." But do not dwarf plants ever compete? My experience of the South Downs, where plants are for the most part considerably dwarfed, is that the struggle between them is a severe one. Yet their flowers and foliage are fully exposed to sunlight and insects, as well as to severe gales of wind. Mr. Cockerell also appears to forget that what is true for one plant is true for another, and each must try to overtop all the others.

I would venture to warn our younger naturalists most earnestly against this *facilis descensus* of *a priori* reasoning without facts or verification. It has been the bane of metaphysics; and when a scientific man like Dr. Weismann puts forth, in the name of science, most deplorable illustrations of it in his late attempt to apply his theory to plants, it is time that some one should venture to protest.

In reply to his request, I would refer Mr. Cockerell to M. Verlot's pamphlet "Sur la Production et la Fixation des Variétés," in which he describes his method of creating and fixing dwarf plants by sowing seed late in the season. Also to M. Roujou's experiments in selecting the smallest seeds of plants (*Journ. d'Hist. Nat. de Bordeaux et du Sud-Ouest*, 1884). Mr. McNab also raised dwarf rhododendrons by using pollen from the smallest stamens. Want of space forbids me adding more on the subject. GEORGE HENSLOW.

The Natural Selection of Indian Corn.

In a former letter I had occasion to mention that *Zea maïs* varies in its period of maturing, and that at certain altitudes and latitudes, only some of the varieties (*i.e.* the early maturing) are able to mature at all, the rest being absolutely eliminated by natural selection in a single generation. A few days ago I received, through the kindness of Mr. James Fletcher, the new (1891) Report on Experimental Farms for 1890, published by the Canadian Government, in which are numerous statistics of experimental planting in different parts of the Dominion. On p. 296, Mr. T. A. Sharpe gives an account of the result of planting twenty-nine different varieties of Indian corn at Agassiz, British Columbia, which perhaps deserves notice, as illustrating the above-mentioned facts in a particularly clear way. Of the varieties planted (all exposed to the same kind of environment), the majority did not form any ears at all. Some formed very small ears, and others reached various stages of maturity, but only a very few actually matured.

For example, I will quote some of them:—

No. 1. Moore's Early Concord, corn matured, one of the best.
No. 3. Early Adams, corn matured to glazing stage.
No. 6. Mitchell's Extra Early White Flint, produced some matured ears.
No. 11. Marblehead Sugar, matured corn, ears very small.
No. 12. Narraganset, sweet, corn did not fill to tips of cob.
No. 14. Chester Co. Mammoth, no corn formed.
No. 21. Golden Dent, no ears formed.

T. D. A. COCKERELL.

3 Fairfax Road, Bedford Park, Chiswick, W., May 10.

The Soaring of Birds.

It seems a great pity that the simpler form of this question—wherein birds soaring steadily rise, in a gentle breeze, over a large plain—is needlessly complicated by the flight of sea-birds over waves.

We shall get the solution best by taking the former and less complicated case, wherein the pelicans, adjutants, cyrus, vultures, &c., slowly rise, by soaring alone, to great heights, under conditions where up-rushes of air are quite out of the question.

Upper Asam is a dead level, some 60 miles wide by 200 long, and over this area, wherein these birds rise by soaring alone, the air-drift is almost invariably from north-north-east, or else south-west, and at about 5 to 10 miles an hour. They do not seem to rise in a dead calm, nor yet in stormy weather, and I take it the desideratum is a slow air-drift, or gentle *steady* breeze.

That there are no up-rushes of air, I have fairly good proof in the small tufts of cotton, from the *Bombyx malabaricum*, which cross the field of my telescope when examining the Noga Hills at 10 to 20 or 30 miles; these are always beautifully horizontal at elevations from 200 to 2000 feet, coming from the plains and hills north-east of us.

So that out here there is no complication of the case by vertical movements of the air, as at sea. The question is not how large birds sustain themselves (without flapping their wings) in a wind, when there are rising and falling and strata of "different velocities"; but how large birds like the cyrus, adjutant, pelican, and vulture can rise from 300 to 3000 feet, in a *steady* breeze, without flapping their wings.

It is not mere flotation; they have to *raise* 20 or 30 pounds some 2000 feet, in addition to what the albatross does.

Surely this is the major question, at once simpler to see, and more difficult to answer.

In NATURE (vol. xxiii. p. 10) I drew attention to this, and sent a small diagram, to show how I thought it was done. I have frequently observed the phenomena since, and see no reason to modify my views.

Firstly, these large birds do not soar in a dead calm, or a storm, or during high winds. They prefer a steady breeze.

Secondly, they rise from the ground, by flapping the wings, and continue this till they are 100 or 200 feet up, and then begin to soar, in right or left hand spirals, 100 or 200 yards across. At each lap they rise 10 or 20 feet, and make as many yards leeway, drifting slowly *with the wind*, and continue thus to rise until out of sight above.

With a good telescope a bird can be easily followed after a little practice, and the only motion which can be seen is slight and occasional movement of the tail, in steering.

The legs (of the waders) are extended at full length behind, the neck thrown on the back, and beak projecting over the breast . The tips of the primary wing-feathers are always well separated in different planes, , and strongly curved up, thus,  evidently under great strain.

The lifting power is evidently applied to them mainly, and the plane of the outspread wings is not horizontal, but forms part of an obtuse, inverted cone, as though a little centrifugal force was implicated.

The speed of the bird is always greater than the breeze, and the resistance is unequal on opposite sides of the loop of the spiral; least when it travels with the breeze, and greatest when on the opposite half, meeting it.

It seems to me the solution is that, when going with the wind, the bird gathers momentum by going down a slight incline, and when it turns and meets the breeze, this extra momentum is used in lifting the bird and carrying it over a *shorter* course. Thus it starts the next lap at a *slightly* higher level, but some 20 yards to leeward. Variation of the speed of the wind at different levels is here quite out of the question; the bird, too, keeps to its steady spiral, and as steadily ascends at each lap.

I feel sure that Prof. Tait, Sir W. Thomson, and Lord Rayleigh will find the case I state a more profitable one to study than the erratic flight or floating of sea-birds. The telescope I use to watch and follow these birds when soaring is a 3·5" O.G. power 50, with long tripod legs, and on a mattrass below I find no difficulty in keeping a bird in the field, if at 1000 feet up. My own idea is that all these birds go up there to sleep or doze.

Sibsagar, Asam, March 30. S. E. PEAL.

ON SOME POINTS IN THE EARLY HISTORY OF ASTRONOMY.[1]

III.

WE now come to the important point for our present inquiry—the direction in which the temple is built, or, technically, its orientation. Confining ourselves for the moment to Karnak, is there any meaning in the direction of that line, some 500 yards long, which is obviously the main feature of the building, and to which all parts are accessories?

How can we instrumentally determine this? I have the necessary apparatus here, and the question may be answered in a few minutes; we have simply to determine either the azimuth or the amplitude (and as we have seen one of these gives the other) of the point of the horizon towards which this long line is directed.

The azimuth compass is an instrument familiar to most of you. It consists of a magnetic needle fastened to a card carrying a circle divided into 360°, which can be conveniently read by a prism when the instrument is turned toward any definite direction marked by a vertical wire.

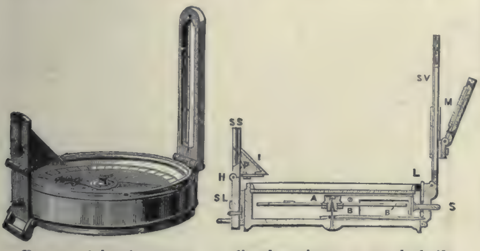

FIG. 11.—Azimuth compass. SV, direction pointer; M, sun shade (for observations of sun); I, reading prism; A B, graduated card with attached compass-needle.

A theodolite armed with a delicately hung magnetic needle which can be rotated on a vertical axis will do equally well; it has first of all to be levelled; there is a little telescope with which we can see along the line.

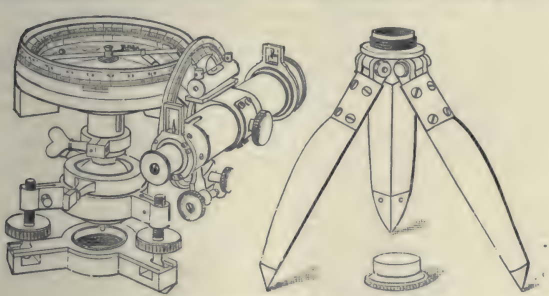

FIG. 12.—Compass theodolite and tripod.

When we wish, for instance, to observe the amplitude of a temple, the theodolite is set up on its tripod in such a position that we can look along the temple wall or line of columns, &c., by means of the telescope. We then get a magnetic reading of the direction, after having unclamped the compass; the compass showing the angle made between the line and the magnetic north (or south), as in the azimuth compass.

Having made such an observation as that I have described, the next thing we have to do is to determine astronomically the real north, which is the only thing of value. There are two ways of getting this *astronomical* bearing or azimuth.

It is sad to think how much time has been lost in the investigation of a great many of these questions, for the reason that the observations were made only with reference to the magnetic north, which is vastly different at different places, and is always varying; few indeed have tried to get at the astronomical conditions of the problem. Had this been done either by the French or Prussian Commissions to which I have referred, it is perfectly certain that years ago the solstitial orientation of Karnak and other temples which I shall have to demonstrate to you would have been long known to all scholars.

If the magnetic variation has been determined for the region we may use a map. Such a map as that shown in Fig. 13 gives us the lines along which in the British Isles the compass variation west of north reaches certain values. From such a map for Egypt we learn that in 1798 a magnet swung along a line extending from a little to the west of Cairo to the second cataract would have had a variation of 12° to the west; in 1844 of 8° to the west; and at the present time the variation is such that observations made along the same part of the Nile valley will have a variation closely approximating 5° to the west. By means of such a map it is quite possible to get approximately the astronomical bearings of all temples which were observed by the French in 1798 or by the Germans in 1844, or which can be observed in the present day.

If we are not fortunate enough to possess such a map, the theodolite will enable us to observe the direction in which the sun culminates at noon. This gives us the south point astronomically. From observations of the pole star at night, the astronomical north can be determined. From either of these observations the magnetic variation is obtained without any difficulty.

This being premised about the method, we next come to the results. The amplitude of the point to which the axis of the great temple at Karnak points is 26° N. of W., which we learn from the table already given is precisely the amplitude of the place of sunset at the summer solstice. The amplitude of the point to which the axis of the small temple points is 26° S. of E., exactly the position of sunrise at the winter solstice.

There is more evidence of this kind. Abydos, one of the oldest temples in Egypt, built, according to tradition, by the servants of Hor, is now, it is true, a heap of ruins, the brick walls best showing its direction; but it is possible to gather the orientation of it by these guiding lines. It is 27° N. of W.—as it should be, being in a higher latitude than Karnak—and evidently was oriented to the solstice.

At Abydos, then, as at Karnak, we get exactly, within a degree, the amplitude shown in the tables for the sun in the Nile valley at sunset at the summer solstice. So that the Egyptians who were employed in building those temples must have known exactly what they were going to do, and what they did was to build a temple such that the sun at setting should, at the summer solstice, pour its light along the axis of the temple. If Maspéro and the great authorities in Egyptian archæology are right—namely, that the Abydos temple was founded before 4000 B.C.—and if we can depend upon the French figures, we are driven to the conclusion that we have in this temple a building which was orientated to the solstitial sunset place in the valley of the Nile. The Nile valley holds other solar temples besides those we have named, but it is best to fully study Karnak; instead of being a mere heap, the orientation of which is obtainable only by the general lie of the remains, this temple is still in such preservation that the Germans, in the year 1844, could give us an infinite number of details about it, and locate the position of the innumerable courts. Its orientation to the solstice we can claim as an early astronomical observation. So it is quite fair to say that, many thousand years ago at all events, the Egyptians were perfectly familiar with the solstices, and therefore more or less fully with the yearly path of the sun.

---

[1] Continued from p. 11.

But so far we have only dealt with solstices. Did the Egyptians know anything about the equinoxes? Certainly. Nothing is more remarkable than to go from the description and the plans of such temples as we have seen at Abydos and Karnak to regions where, apparently, the thought is totally and completely different, such as we find on the Pyramid Plains at Ghizeh; the orientation lines of the German surveyors show, beyond all question, that these structures are just as true to the sun-rising at the equinoxes as the temples at Abydos and Karnak were to the sun-rising and setting at the solstices, and the Sphinx was merely a mysterious nondescript sort of thing which was there watching for the rising of the sun at an equinox, as the Colossi of the plain at Thebes were watching for the rising of the sun at the winter solstice.

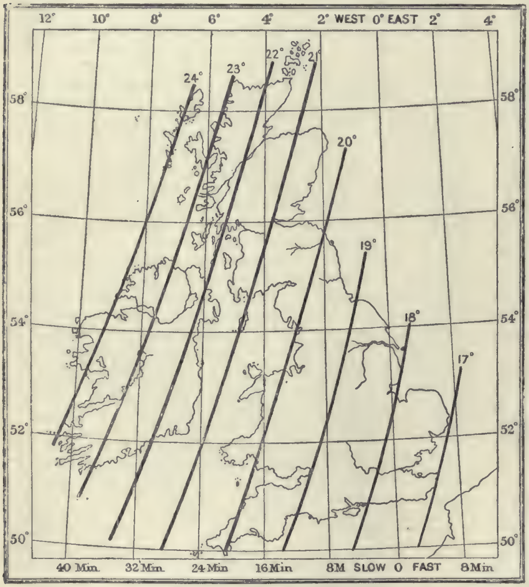

Fig. 13.—Map of British Isles showing the magnetic variation.[1]

The observations which have been made in Babylonia are very discordant among themselves, and at present it is impossible to say, from the monuments in any of this region along the Euphrates valley, whether the temples indicate that the solstices were familiar to the Babylonians; but no doubt some of the temples were as perfectly squared to the equinox as some walls at Memphis or the Pyramids at Ghizeh; and certainly there is no doubt that as early as Solomon's time the temple at Jerusalem was orientated to the east with care. We find there that the direction of the axis of the temple shows the existence of a cult connected with the possibility of seeing the rising of the sun on the day of an equinox, possibly at the time which we now call Easter.

All the doors being opened, the sunlight would penetrate over the high altar, where the sacrifices were offered, into the very Holy of Holies, which we may remember was only entered by the High Priest once a year.

Have we any other evidence except the evidence afforded by temples? Yes. It has been stated that we have no temple evidence from China, but there is a good deal of written evidence, and there is no doubt that in China the solstices and the equinoxes were perfectly well known 1100 years B.C. Was it difficult to obtain this knowledge? Did it indicate that the people were great astronomers? Nothing of the kind; nothing is so easy as to determine a solstice or an equinox.

We know from the Egyptian tombs that their stock-in-trade, so far as building went, was very considerable; they had squares, they had plumb-lines, they had scales, and all that sort of thing just as we have. Suppose an Egyptian wished to determine the time of an equinox. He would first of all make a platform quite flat; he could do that by means of the square or plumb line; then he would get a ruler with pretty sharp edges (and such rulers are found in their tombs), and in the morning of any day he would direct this ruler to the position of the sun when it is rising and he would draw a line; he would do the same thing in the evening when the sun set; he would bisect the angle made by these two lines, and it would give him naturally the north and south points, and a right angle to those would give him the east and west. So that from observation of the sun on any two days in the year he would practically be in a position to determine the position at which the sun would rise and set at the equinox.

There is another way of doing it. Take a vertical rod. Suppose that the sun is rising, let the rod throw a shadow; mark the position of the shadow; at sunset we again note where the shadow falls. If the sun rises exactly in the east and sets exactly in the west, those two shadows will be continuous and we shall have made an observation at the absolute equinox. But suppose the sun not at the equinox, a line joining the ends of the shadows equally long before and after noon will be an east and west line.

It is true that there may be a slight error unless we are very careful about the time of the year at which we make the observations, because when the sun is exactly east or west at the time of rising or setting it is moving most rapidly. So it is better to make the above observations of the sun nearer the solstices than the equinoxes, because the sun changes its declination most quickly at the equinoxes.

Such a rod as this, which I may state is sometimes called a *gnomon*, may be used with another object in view: we may observe the length of the shadow cast by the sun when it is lowest at the winter solstice, and when it is highest; at these two positions of the sun obviously the lengths of the shadows thrown will be different. When the sun is nearest overhead in the summer the shadow will be least, when the sun is most removed from the vertical the shadow will be longest.

The day on which the shortest shadow is thrown at noon will define the summer solstice; when the shadow is longest we shall have the winter solstice.

This in fact was the method adopted by the Chinese to determine the solstices, and from it very early they found a value of the obliquity of the ecliptic.

It may be said that it is only a statement, and that the record has been falsified; some years ago anyone who was driven by facts to come to the conclusion that any very considerable antiquity was possible in these observations met with very great difficulty. But the shortest and the longest shadows recorded (700 years B.C.) do not really represent the true lengths according to recent knowledge. If anyone had forged these observations he would state such lengths as people would find to-day or to-morrow, but the lengths given were different from those which would be made to-day. Laplace, who gave considerable attention to this matter, determined what the real obliquity was at that time, and proved that the record does represent an actual observation and not one which had been made in later years.

---

[1] For Figs. 11–13 I am indebted to the kindness of Mr. Stanley, Great Turnstile, Lincoln's Inn Fields.

The solstices and the equinoxes were therefore in all probability thoroughly known to the Egyptians 4000 years B.C., perhaps even 5000. We are then justified in considering that the temples at Abydos and at Karnak are really solar temples. The Egyptians marked the solstices and the equinoxes not only by their temples but in their calendars, which these temples enabled them to construct. The Chinese had also this knowledge, but we have no information that they possessed it at so early a date.

In the next place, then, I propose to make a special study of the temples at Karnak, because they are those which are most capable of minute investigation. I do this in order to see whether any other indications can be obtained of any higher knowledge possessed by the Egyptians of those early times.

I must again point out that we deal with the solstices in the case of the temples at Abydos and Karnak, and with the equinoxes in the case of the pyramids, some mounds in Babylonia, and the Temple at Jerusalem. Since the labours of the French and Prussian Governments who have given such full records of Karnak, a memoir on the temples has been published by Mariette, which gives us not only plans, but precious information relating to the periods at which, and the kings by whom, the various parts of the temples were constructed or modified.

We may begin by the general plan of Thebes. We find there a perfect nest of temples. No doubt those which are still traceable form only a very small portion of those which once existed, but however that may be, I have now only to call attention to one or two among them. In the general plan we see indications that on both sides of the Nile there were temples pointing to those special amplitudes which I have before referred to. What we have first to do is to refer to the solstitial temples, those which point to 26° N. or S. of E. or W., in which we have undoubtedly indications of the early attempts to observe, or to worship, the sun at sun-rising and at sun-setting, at the critical times—the solstitial times of the year.

The first point that I wish to make is that these temples—whatever views may be entertained with regard to their worship or the ceremonial in them—were undoubtedly constructed among other reasons for the purpose of obtaining an exact observation of the precise time of the solstice. The priests having this power at their disposal, would not be likely to neglect it, for they ruled by knowledge. The temples were, then, astronomical observatories, and the first observatories that we know of in the world.

If we consider them as horizontal telescopes used for the purpose I have suggested, we at once understand the long axis, and the series of gradually narrowing diaphragms, for, the longer the beam of light used, the greater is the accuracy that can be obtained.

It is worthy of note that the direction of the temple at Karnak is quite independent of the locality, it has nothing to do with the presentation of the temple to the Nile or to any other particular part of the landscape, and that point, I think, is absolutely settled by the consideration that we have temples at the same amplitude in different localities up and down the Nile Valley, where, although they are parallel to each other, their presentation to the river in the different localities is very various.

What then was the real use of these pylons and these diaphragms? It was to keep all stray light out of the carefully roofed and darkened sanctuary; but why was the sanctuary to be kept in darkness?

Independently of ceremonial reasons—there is a good deal to be said under that head—it is quite clear that the darker the sanctuary the more obvious will be the patch of light on the end wall, and the more easily can its position be located. It was important to do this on the two or three days near the solstice in order to get an idea of the exact time at which the solstice took place. We find that a narrow beam of sunlight coming through a narrow entrance some 500 yards away from the door of the Holy of Holies would, provided the temple were properly orientated to the solstice, and provided the solstice occurred at the absolute moment of sunrise or sunset according to which the temple was being utilized, practically flash into the sanctuary and remain there for about a couple of minutes, and then pass away. The flash would be a crescendo and diminuendo, but the whole thing would not last above two minutes or thereabouts, and might be considerably reduced by arrangements of curtains. Supposing the solstice did not occur at the precise moment of sunrise or sunset, and provided the Egyptians by any means whatever were able to divide the days and the nights into more or less equal intervals of time, two or three observations of the sun-rising at the solstice on three different mornings, or of the sunset at the solstice on three different evenings, would enable a careful observer to say whether the solstice had occurred at the exact moment of sunrise or at some interval between two successive sunrises, and if the latter, what that interval was.

I now come to my next point, which is that here we have the true origin of our present means of measuring time—that our year as we know it was first determined in these Egyptian temples and by the Egyptians. We have seen that it did not require any great amount of astronomical knowledge to determine either the moment of the solstice or the moment of the equinox. I think you will agree with me that the most natural thing to begin with was the observation of the solstice, for the reason that at the solstice you can watch the sun day after day getting more and more north or more and more south until it comes to a standstill. But for the observation of the equinox, of course, the sun is moving most rapidly either north or south, and therefore it would be more difficult to determine in those days the exact moment, so that I have little doubt that what they attempted in the first instance was to mark the absolute moment of the solstice. If that be so, and if Maspéro is right that Abydos was built before Menes, then we know definitely that the Egyptians could and did observe the solstices, and knew what they were doing, 7000 years ago.

Before I say anything more about the use of these temples in determining the year, it is worth while to note how very different the treatment of this subject was in Egypt to what it was in Chaldæa and Babylonia and among the Jews. We do of course in the Egyptian inscriptions read of the moon, but in Chaldæa it would seem that the moon was the chief thing worshipped, and it was thus naturally the chief means used for measuring time, and, as far of course as months were concerned, this was quite right. In Chaldæa, where they were not dependent upon the rising of the Nile, and where much desert travel had to be undertaken at night, the moon and the month were the points considered, and the sun was hardly regarded at all from that point of view. An interesting point connected with this is that, among any of these ancient peoples, the celestial bodies which gave them the longest period of time by which they reckoned were practically looked upon in the same category.

Thus, for instance, in Egypt the sun being used, the unit of time was a year; but in Chaldæa the unit of time was a month, for the reason that the standard of time was the moon. So that when people began speaking about periods of time it was quite easy for one nation to conceive that a period of time was a year when really it was a month, and *vice versâ*. It has been suggested that the years of Methuselah and other persons who are stated to have lived a considerable number of years were not solar years but lunar years—that is, properly, lunar months. This is reasonable, since if we divide the numbers by 12 we find that they come out very much the same length as lives are in the present day.

The Egyptians, taking the sun as their measurer of time, began very early with a year of 360 days. For some reason or other they divided these 360 days into months, probably with some lunar connection, so that they had 12 months of 30 days. Now, we know that that is not the true length of the year, and it is clear that any nation which uses such a year as that will find its festivals going through the year. Further, such a year as that is absolutely useless for the agriculturist or the gardener, because after a time the same month, to say nothing of the same day of the month, will not mean reaping-time, will not mean sowing-time, or anything else. So that this 360-day year did not last very long; so long as it lasted, however, they knew that they got the seasons back to months of the same name in a period of 70 years.

This method led to complications, which possibly may have had something to do with the building of these temples. Egypt being exclusively the gift of the Nile, you can quite understand that their earliest calendar would be connected with the Nile, and so one finds it. We and other peoples occupying the zone in the north divide the year into four seasons; the Egyptians divided it, and still divide it, into three: they have four months of the flood of the Nile, then they have four months after the Nile has retired, in which they do their sowing, and then they have other four months which they call their summer, in which they gather their harvest.

We began, then, with a year of 360 days, and, having 360 days instead of 365¼, we had a cycle of 70 years, and during that cycle each day of the year meant something different with regard to the advance of the seasons, and with regard to the work of the agriculturist and the gardener to what it had meant in the preceding year. But this state of things did not last long. The 1st of the first month fell at the summer solstice on June 20, and the reason that it fell then was, that the inundation of the Nile reached Memphis on that day. Whether with the help of the temples or not, they soon got very much nearer, and changed the year of 360 for one of 365 days, which is, roughly, within a quarter of a day of the truth. They had still their 12 months of 30 days, and then they added an extra month of 5 days. With their perfectly orientated temples they must have soon found that their festival at the summer solstice—which festival is known all over the world to-day—did not fall precisely on the same day of the new year, because, if 365 days had exactly measured the year, that flash of bright sunlight would have fallen into the sanctuary just as it did 365 days before. But what they must have found was, that after an interval of four years it did not fall on the first day of the month, but on the day following it. They at once faced this, and found out that 365 days did not exactly make a year, but that they had to do with a quarter day in addition. What the Chinese did was this: every fourth year, instead of adding 5 days to their 360, they added 6 days, and in that way they practically brought the calendar right.

Theory indicated that retaining the 365-day year, the 1st of the first month would come back to its exact relationship to the inundation of the Nile after a period of 1460 years, the 1460 years of course depending upon the quarter being added (365 × 4 = 1460).

This was known in Egypt to the priests alone. They would not allow the year of 365 days, called the *vague* year, to be altered, and so strongly did they feel on this point that every king had to swear when he was crowned that he would not alter the year. We can surmise why this was. It gave great power to the priests; they alone could tell on what particular day of what particular month the Nile would rise in each year, because they alone knew in what part of the cycle of 1460 years they were, and in order to get that knowledge they had simply to continue going every year into their Holy of Holies one day in the year as the priests did in Jerusalem, and watch the little patch of bright sunlight coming into the sanctuary. That would tell them exactly the relation of the true solar solstice to their year, which was supposed to begin at the solstice, and the exact date of the inundation of the Nile could be found by those who could determine observationally the solstice, but by no others.

In reading books on Egypt we come across another cycle which is supposed to be a very mysterious one; in fact it is one which, I think, has not yet been sufficiently investigated, and it is very well worth the trouble of anybody who will give the time. They begin with a year of twelve months, each of which has thirty days, thus giving 360 days; this was found not to work. They then tried 365 days, but that also would not work, because then the first day of Thoth (their first month) would only indicate the inundation of the Nile one year out of 1460; and then the priests interpolated the other day and got the cycle right, but it was not yet quite right. In the time of Hipparchus 365·25 did not really represent the true length of the solar year; instead of 365·25 we must write 365·242392—that is to say, the real length of the year was a little less than 365¼ days.

Now the length of the year being a little less, of course we should only get the absolute coincidence of the 1st of Thoth with the inundation of the Nile in a longer period than the 1460 years cycle; and, as a matter of fact, the 1460 years had to be expanded into 1506 to fit the months into the years with this slightly shortened length of the year; so we have a period which is called *sothic*, of 1460 years; and a period which is called *phœnix*, of 1506 years.

There is a great wealth of interest connected with the uses of the temples from the point of view of worship, but that does not concern us here, except that it is intimately connected with the next part of the subject, for I have next to point out that it necessitated in Egypt, Chaldæa, and elsewhere contemporaneous observations of the stars. I therefore now pass from the sun to the stars.

J. NORMAN LOCKYER.

(*To be continued.*)

FORESTRY IN NORTH AMERICA.

IN continuation of the notes under the above heading which appeared in NATURE last January, I wish to refer to a splendid paper[1] recently read by Sir Dietrich Brandis, F.R.S., to the Natural History Society of Bonn. It consists chiefly of a compilation from Dr. Mayr's book, "Die Waldungen von Nord America" (Munich, 1890), and from works by Prof. Sargent Bernhard Fernow, the present Chief of Forestry at Washington, and some other authors, as well as from the Agricultural Reports of the United States.

Dr. Mayr is the son of a Bavarian State forest officer, and, after studying forestry and botany at Munich, he was sent, at the expense of the Bavarian Government, to observe in their native forests, at different ages, certain important

---

[1] "Der Wald in den Vereinigten Staaten von Nord America," von Dr. D. Brandis in Bonn, 1891. (Sonder Abdruck aus den *Verhandlungen des Naturhistorischen Vereins*, 47 Jahrg.)

North American forest trees, experimental plantings of which have from time to time been made in Germany. After spending seven months on these researches, and extending his tour through Japan, Java, Ceylon, and Northern Hindustan, Dr. Mayr returned to Germany in 1888, and was shortly afterwards appointed Professor of Forestry and Forest Botany at the College of Agriculture and Forestry at Tokio in Japan. The present writer had the great pleasure of accompanying him in January 1888 for about three weeks through some of the coniferous and oak forests of the North-Western Himalayas and the subtropical forests of the lower hills near Dehra.

After leaving Germany a second time for Japan, Dr. Mayr had a further opportunity of visiting North America, and thus has twice traversed the length and breadth of the country between the Dominion of Canada and Mexico.

Mayr treats of the demands of the most important North American trees as regards climate and soil, with a summary account of their anatomical structure and of the physical and technical qualities of the most important woods, and his book contains numerous illustrations. He also gives lists of destructive fungi and insects observed by him on the different species.

Brandis has some criticisms to mete out for a few somewhat rash generalizations made by Mayr. These are that evergreen broad-leaved (not coniferous) forest requires a higher winter temperature than deciduous forest, and that deciduous forest vegetation is always absent in tropical countries on account of the uniformity of the climate throughout the year. Brandis shows clearly, from a comparison with the deciduous forests of teak and other species in India, Burma, and Java, that this statement will not hold wherever there is a prolonged dry season, which renders the trees leafless for a certain period of the year.

Another statement of Mayr's controverted by Brandis is that conifers never grow in tropical countries except where the altitude renders the climate non-tropical, and that in North America they have longer needles, supply heavier timber, and contain the more resin, the nearer they grow to the tropics. The latter statements may be true for *Pinus australis*, the pitch pine of the Southern States of North America, but do not hold good in India, where the *Pinus longifolia* of the Himalayas has the longest needles and probably yields as much resin as the tropical pine (*P. Merkensii*), which, however, has the heaviest wood of all the Indian pines, and grows in latitude 17° N., in Tenasserim, at about 600 feet above sea-level, in an absolutely tropical climate.

Mayr's statement that oranges will only grow to perfection in a hot dry climate is also not true for India, as oranges of splendid flavour are grown in enormous quantities in the damp lower hills below Cherapunji, in Assam, where the rainy season lasts for eight months, as well as in the dry regions near Delhi, and the comparatively dry country near Nagpur, in the Central Provinces of India.

Apart from these criticisms and an interesting discussion on the origin of prairies, we find in Brandis's paper a most complete account of the distribution of North American forest trees.

Forest vegetation is much richer in North America than in Europe, containing about 412 species, distributed as follows:—

Atlantic region	176
Pacific region	106
Common to both	10
Central region on and surrounding Rocky Mountains	46
Tropical species near the coasts of Florida ...	74
	412

as against 158 species in Europe.

At least six North American species of forest trees, according to Brandis, are also indigenous in Europe, being—

Cercis canadensis = *Siliquastrnm*
Diospyros virginiana = *Lotus*
Celtis occidentalis = *australis*
Platanus occidentalis = *orientalis*
Ostrya virginica = *carpinifolia*
Castanea americana = *vulgaris.*

All these species now grow naturally in Europe south of the Alps, and since many American forest genera existed in Europe in Tertiary times, whilst only five European forest genera (Ceratonia, Laburnum, Olea, Syringa, Laurus) are not found in America, it is possible that other species formerly common to both countries were destroyed in Europe north of the Alps by the Glacial epoch.

It would take too long to describe each region in detail, and I must here merely glance at them in the briefest manner.

A small outlier of the West Indian tropical flora extends into the south of Florida, and is followed by a broad zone of evergreen broad-leaved forest, of which *Magnolia grandiflora* is the chief representative. We then get the pitch pine forests on the sandy formations of Florida, Georgia, North and South Carolina, extending westwards to Alabama and Mississippi. The wood of the pitch pine (*P. australis*) is the best coniferous wood in the world, but the forests are being utterly ruined. They are tapped in the most wasteful manner for turpentine, 8,000,000 dollars being the estimated local value of the annual return. More wood is burned than is utilized, and, according to Mayr, already wide belts of white sterile shifting sands border both sides of the railways of the Gulf States, showing what the poorer tracts of the country will come to, if the farmers do not give up their pernicious habit of burning thousands of square miles of forest every year.

Another tree of the Southern Atlantic zone is the swamp cypress (*Taxodium distichum*), growing on annually inundated land, and presumably safe from fire, if not from ill-regulated and wasteful felling.

The valuable pencil cedar (*Juniperus virginiana*) also flourishes at its best in the Southern Atlantic region, but grows almost everywhere in the United States and British America, from latitude 54° southwards. To the north and in the prairies it has, however, only a stunted growth. Hardly any sound wood of this species is now procurable, as I learned last year from Messrs. Faber and Co. at Nuremberg. Next to this zone comes the description of the broad-leaved deciduous forest of the temperate region, containing many oaks, walnuts, hickories, and the tulip tree (*Liriodendron tulipifera*). The heavy seeded trees are found chiefly in the south, and lighter seeded ones, as maples, birches, and elms, more to the north.

There is a long account by Brandis of the prairie region, and the region of thinly-stocked forest bordering on it; and it appears that here, as cultivation extends, and the fires do not sweep over such vast extents of land as they did formerly, woods of Mesquit bean (*Prosopis juliflora*), and other trees are spreading by seed or coppice shoots, in Western Texas, and also in Wisconsin, Illinois, Iowa, and other States. Much has been done in the prairie region by plantations, and these succeed admirably wherever the climate is sufficiently moist; but in the central and western parts of Kansas all planting has hitherto failed, owing to the extremely dry climate.

In the northern pine zone of the Atlantic forest region, *Pinus Strobus*, the Weymouth or white pine is the most important species, and formerly covered enormous tracts from the Gulf of St. Lawrence to North Georgia, and beyond the sources of the Mississippi. At present, the only considerable supply of white pine is in Canada, and in the lake districts of the States of Michigan, Wisconsin, and Minnesota. The timber operations in the white pine forests have only one object, which is to bring as much timber as possible out of the forest in the shortest possible time, and to make money. Only the best trees are felled, and the rest burned. A forest after a timber gang has left it presents a remarkable appearance: between the standing blackened and partially charred stems of the broad-leaved and other trees which have not been felled are the stumps of the felled pines, whilst the ground is covered with wood, which would not have paid for its removal, and rots, or is burned by the annual fires.

In 1880, there were in the three lake districts 7000 million cubic feet of standing white pine timber, whilst in the last ten years 6205 millions of cubic feet have been felled and exported, 750 millions in 1889 alone. There is, therefore, little more left than can be exported in a single year. Many of the large saw-mills have already been obliged to stop work, or get timber from Canada. Chicago, which owes its rapid rise to the timber trade, imports yearly 166,000,000 cubic feet of white pine timber. This is about three-fourths of the whole forest yield of Prussia, the produce of 6,750,000 acres or 10,547 square miles of forest. Besides the Weymouth pine, *Pinus Banksiana*, the grey pine, and *Pinus resinosa*, and various broad-leaved trees are found. The sub-Arctic region of Alaska and British North America is poor in species; *Picea alba* and *nigra*, the white and black spruce, being characteristic trees.

Merely glancing at the North Mexican forest region, with forests of *Prosopis juliflora*, and grassy tracts containing gigantic cacti, and *Yucca baccata*, a palm lily, attaining 40 feet in height, we come to the Pacific forest region, where the Douglas fir, *Pseudotsuga Douglasii*, is the most important tree, and yields, in suitable localities, perhaps the greatest quantity of timber per acre of any known species.

We finally come to the red wood forests of the Pacific coast, where *Sequoia sempervirens* prevails, its congener *Sequoia gigantea* only occurring over a limited area. Unregulated fellings also prevail in the Douglas and red wood forests, and their supply cannot last much longer.

Besides the wholesale destruction of forests which goes on in America, and has already driven the United States to remove all duty from Canadian wood, the most appalling destruction is now being annually caused by the floods which pour down the slopes of the mountains, bringing down boulders, stones, and gravel on the cultivated lands below. Mayr has seen standing trees covered with mud up to a height of 15 feet in some of the Southern and Central States, whilst hundreds of magnificent trees lay uprooted in the full vigour of their growth. This can clearly be traced to the destruction of the hill forests.

How long will rulers of the United States shut their eyes to the appalling waste of the resources of their country which is still rampant! Brandis hopes that private capitalists may invest their money in forests, tempted by the rapid rise in the price of wood, and may manage them properly; but all European experience points to the necessity of State forests, and a trained State Forest Service to manage them, as the only efficacious remedy against the impoverishment of the soil and natural resources of America. W. R. FISHER.

DAILY INTERNATIONAL WEATHER CHARTS.

AT the meeting of the Meteorological Congress at Vienna in September 1873, General Myer, the Chief Signal Officer of the United States Army, submitted the following proposal:—

"That it is desirable that, with a view to their exchange, at least *one* uniform observation of such a character as to be suitable for the preparation of synoptic charts be taken and recorded daily and simultaneously at as many stations as practicable throughout the world."

Although various suggestions had been made before, and synoptic charts had been previously constructed for large areas, this proposal was a bold step in advance, as the charts hitherto published—those of the English Meteorological Office excepted—were mostly synoptic only, but not strictly synchronous, whereas the plan now proposed was to treat the whole observational area of the globe as a unit, and to represent the actual conditions existing at the same instant of physical time.

The proposal was well received, and on January 1, 1875, General Myer was able to publish his daily International Bulletin, and to supplement this, on July 1, 1878, by the daily International Weather Map. These publications were continued until the end of March 1884, after which time the daily Bulletin was discontinued, but the chart was issued on an enlarged scale, containing data referring to pressure and wind direction and force at all reporting stations in the northern hemisphere and over the northern portions of the Atlantic and Pacific Oceans, and this has been published up to the end of December 1887. We have before referred to the ability with which this great undertaking has been carried out by the Signal Service. The necessity of obtaining strictly simultaneous observations was generally acknowledged after the discovery of Buys Ballot's law of the relation between wind force and barometric pressure, about the year 1857, and it is almost entirely due to the construction of synoptic charts over large areas that so much progress has been made in weather prediction in the last quarter of a century. This progress would hardly have been possible while each country dealt exclusively with its own area, notwithstanding the great advance made over the old system of dealing with means of observations by the publication of telegraphic weather reports and weather charts. But notwithstanding the progress already made, we are still unable to foresee what may occur for more than a day or so in advance. Much more research is required, and the thousands of observations now taken on land and sea over the globe should be plotted at least once a day. We should therefore much regret the discontinuance of such work as that now before us, which deals with nearly half the globe.

To take one or two of the facts shown by the charts themselves: the very severe gale which visited these islands on December 8 and 9, 1886, in which about the lowest barometer reading on record was observed, will be remembered in connection with the capsizing of the Southport and St. Anne's lifeboats near Formby, resulting in the loss of twenty-seven lives out of twenty-nine which constituted the two crews. In a paper upon this storm, read before the Royal Meteorological Society on April 20, 1887, by Mr. C. Harding, it is stated, after a careful examination of the materials then available, that "the Atlantic was in such a disturbed condition at this time that it is not possible to track the passage of the storm across the Atlantic with any certainty." The daily International Charts, however, show the position of the storm day by day, and also that it did actually cross the Atlantic from shore to shore, and was central over the Gulf of St. Lawrence on December 3.

Another instance of remarkable weather, it will be remembered, occurred in June 1887—the Jubilee year; the weather was remarkably dry and fine in this country, there being an extraordinary drought of about thirty days. The charts for that period show that similar anticyclonic conditions also embraced a very large part of the eastern portion of the Atlantic, and extended abnormally over a portion of Europe; while the travelling disturbances are plainly shown to be confined to the American side of the ocean.

It is only Government organizations that can undertake the laborious work of producing such charts; but when they are published, the matter should not be left there: the meteorologist should make use of the materials provided for him, and endeavour to solve the problems which underlie weather changes and the general movements of the atmosphere.

JOSEPH LEIDY, M.D.

THIS well-known American naturalist was born on September 9, 1823. He very early in life showed a fondness for collecting and observing insects, one of his first contributions being a paper on the mechanism which closes the membranous wings of the genus Locusta, published in 1845 in the Proceedings of the Academy of Natural Sciences of Philadelphia. Having taken his degree in medicine, he devoted himself more and more to the study of natural history, and few men of any nation have left behind them a longer list of work done than this distinguished man, whose death we announced in a recent number. Leidy was gifted with great powers of observation, he possessed a correct eye and steady hand for the delineation of whatever objects he was observing, he was endowed with a faculty for work; and as he had also an excellent memory, one reflects upon his half-century of work with less of surprise than admiration. To give an account of his writings would be to write a volume, to give but their titles would be to fill many of our columns, so that it must suffice to call to mind rather the subjects about which he wrote than the writings. Commencing with a study of entomology, and working more at the anatomy than at the general morphology of insects, he quickly passed on to the study of the entophytic worms, his "Flora and Fauna within Living Animals," published as one of the Smithsonian Contributions in 1852, having made its mark at the time. Then he took up the fresh-water Polyzoa, his labours on which will be understood only when a monograph on this group as inhabiting America comes to be published. Leaving for a time the study of invertebrate forms, he next entered on the field of research among the fossil vertebrates, describing in quick succession a number of remarkable fossil reptiles and fish, and he was the author of the first volume of the quarto series of reports issued by the United States Geological Survey of the Territories, under the title of "Contributions to the Extinct Vertebrate Fauna of the Western Territories." It was during his journeys to the Western Territories, that, not content with investigating the fossil vertebrates of the district, he worked very diligently at the study of the microscopic forms of life which inhabit the waters met with therein, and these researches, so far as one group of animals is concerned, were happily published by the United States Geological Survey in 1879, in one large quarto volume, "The Fresh-water Rhizopods of North America," which is illustrated by forty-eight coloured plates after Leidy's own drawings. This work on its appearance was received with great enthusiasm, and is still a worthy model for a monograph. During all these years, and amid so many and so varied labours, Leidy still discharged his duties as Professor of Anatomy to the University of Pennsylvania, and also of teacher of natural history to the classes of boys and girls at the Swarthmore College. No doubt many of these latter pupils will now call to mind the warm personal interest their master always took in their labours. In one of his books he tells us that since he was fourteen years of age the study of natural history was to him a constant source of happiness; but that on this joy a shadow was constantly cast when he thought how few, how very few, of those around him gave any attention to intellectual pursuits of any kind, and it saddened him to feel that the command "that man shall not live by bread alone" remained so unappreciated by the great mass of even so-called enlightened humanity. The results of Leidy's intellectual pursuits will long remain to testify to the manner of man that he was.

THE SCIENCE MUSEUM.

THE discussion on this all-important question continues in the press. The Whitsuntide holidays have prevented any questions being asked in the House of Commons, where the feeling is very strong against the action of the Government.

As before, we reprint the most important items in the discussion. These consist of letters from Sir H. Roscoe and Profs. Armstrong and Ayrton to the *Times*. We commend to our readers the reference by the latter to Mr. Goschen's treatment of the deputation, and also their judgment as to the present position of science in this country, and the teaching of it in London, as compared with Göttingen and Zürich. No one can speak with greater authority than Profs. Armstrong and Ayrton on this subject.

Our administrative system, however, is such that the present question, which is acknowledged to be of such high importance, is being settled exclusively by officials who are quite ignorant of science. This is not said to their disparagement: it is only a statement of fact. The letters run as follow:—

ONE cannot but feel much sympathy for Ministers, on the one hand pressed by the advocates of scientific and technical education, and on the other nervous at the prospect of not securing the gifts of the munificent but somewhat *exigeant* art donor. But the question is so vitally important from the point of view of science that I feel sure no excuse is necessary if I urge most strenuously that an irrevocable step be not taken without full and careful consideration; and, further, that a definite scheme for providing for the science collections and Science School be formulated before what many of us believe to be a most unwise interpolation of an art gallery, on land which when bought was universally believed to have been acquired for scientific ends, is finally decided on.

At the present moment it is impossible to say under which thimble the scientific pea is housed, and it was no doubt due to this that the discussion which the deputation had with the Chancellor of the Exchequer and Lord President of the Council on Tuesday last was to some extent abortive.

The Chancellor of the Exchequer, in reply to myself on March 18, said:—

"It would be possible to make adequate provision for chemical and physical laboratories on the land between the Imperial Institute Road and the Technical Institute. This site adjoins the east galleries, and it is in these galleries, together with the west and southern galleries, and a proposed cross gallery joining the east and west galleries, that the science collections may ultimately be housed."

But by April 15 the impracticability of the scheme of putting part of the Science School at the south end of the eastern gallery seems to have been discovered. For on that day Mr. W. H. Smith, in reply to Mr. Mundella, propounded another scheme for the Science School, while leaving the collections to be housed in the east and west and cross galleries. He said:—

"A portion of these vacant lands" (facing the Imperial Institute) "can be utilized for the extension of the College of Science and for future growth of the science collections. Additions to the College of Science must in any case take the form of a separate building, divided from the present building by Exhibition Road; and, as access to the lands mentioned above from Exhibition Road will be secured by means of a corridor, the interposition of the Gallery of British Art need have no more serious effect than to increase by some 60 yards (which will be under cover) the distance between the two portions of the Science College."

By the former plan a portion of the Science School would no doubt have been in immediate contact with the splendid picture galleries in which the science objects were to be housed; but it would be far removed from the other part of the school—the Exhibition Road thus becoming a school of peripatetic philosophy. By the latter scheme the two parts of the school would be brought somewhat closer together—less of Exhibition Road and more of covered corridor—but then both portions would be entirely separated from the science collections—two roads to cross, and a walk of half a mile, or thereabouts, to the further part.

When receiving the deputation on Tuesday last, a third scheme was suggested, if not distinctly enunciated, by the Chancellor of the Exchequer, that the Science School extension and the Science Museum should be built on the other side of the plot given to the Art Gallery, but both on the ground recently acquired facing the Imperial Institute.

The two earlier projects having as it were blown themselves up, it is only necessary for me to deal with the last.

It has been argued that the recent Committee on the science collections, of which I was a member, only asked for 90,000 square feet of exhibiting space, and that more than that area can be obtained on the vacant ground opposite the Imperial Institute. But it must be remembered that, as stated by our Committee, this space did not provide for offices, workshops, &c.—a considerable item; that it did not in any way provide for the extension of the Science School; and that it was made some time before an immense impetus was given to technical education by the Technical Instruction Acts and the grants under the Customs and Excise Act of last year.

Now, the vacant ground recently acquired—omitting the strip part of which has already been sold, and the remainder of which is going to be sold for private dwelling houses—is about one-third of the land devoted to the Natural History Museum, and almost exactly of the same area as that already covered by the Natural History Museum buildings, which are shortly to be enlarged.

Is it unreasonable for the scientific man to urge that this vacant land is not too much to provide for the whole range of sciences other than those accommodated in the Natural History Museum; for a proper Museum of Machinery and Inventions; for a large extension of the Science School; and possibly for the collections from the Jermyn Street Museum? Surely there can be but one answer to this question.

Why—and we have never yet obtained an answer to this inquiry—will not the munificent donor be satisfied with another site? Why are the existing physical laboratory and scientific class-rooms to be removed, to allow an art gallery to be interposed between portions of the school?

Even if it be maintained that the ground south of the Imperial Institute Road will provide for the immediate wants of the Science School and collections, is it too much to ask that we should look a little ahead, and not now initiate another hugger-mugger arrangement of the collections and schools at South Kensington, which all will lament in a few years?

10 Bramham Gardens, S.W., HENRY E. ROSCOE.
May 15.

NOTWITHSTANDING that the recent deputation to the President of the Council and the Chancellor of the Exchequer was headed by Sir William Thomson—the man of science whom we in this country regard as first among all others, both on account of his individual achievements and on account of his occupying the representative position of President of the Royal Society—not one single word was said by Mr. Goschen in explanation or justification of the course which he has adopted; we therefore venture, with all respect, to assert that the Royal Society has just cause to complain when one of its Fellows—for Mr. Goschen is one of us—thus treats representations urged by its President.

Where the science collections are to be lodged, where the extensions of the Science Schools are to be placed, are in themselves all-important questions; but a still graver issue remains—whether a weight of opinion of the magnitude represented by the memorial recently published in your columns is to be entirely set aside because an anonymous donor has offered £80,000 *plus* a collection of pictures, valued at another £75,000. That a Government which has at its head a Prime Minister whose interest in science is so marked, should thus disregard the opinion offered by so representative a body of men, is one of those things which even an Englishmen can scarcely understand: in no other country in Europe would such action be possible.

We cannot help thinking that a mistake has been made in calling public attention too exclusively to the housing of the science collections—the extension of the Science Schools appears to be a far more important matter. Attention has often been called of late to what is going on abroad, especially in Germany; to the unremitting attention that is being given to scientific instruction, and to the effect that is being produced on manufacturing industries of all kinds by the high development of science and of the application of every kind of scientific requirement. Unfortunately, in this country such matters have not yet entered into the domain of practical politics. But in the opinion of many among us there cannot be a question that almost superhuman efforts are necessary if this country is to regain the position which it has given away to foreigners by its neglect to apply the highest developments of chemical and physical science to industry.

The accommodation at present afforded by the Royal College of Science laboratories is not only inadequate, but beneath contempt in comparison with that to be found in Continental cities, such even as Göttingen and Zürich, for example; and those of us who have some knowledge of modern requirements know full well that every inch of space on the Imperial Institute Road side of the block of land on which stands the Natural History Museum will before long be required for the purposes of the Royal College of Science. The intrusion of an art gallery into this space would have a most disastrous effect by irretrievably preventing the proper and natural expansion of the Royal College of Science laboratories. This expansion must necessarily be rapid, for science is developing throughout the civilized world at a compound interest rate, and the grants recently made by the Chancellor of the Exchequer in aid of technical instruction must lead even this country to fully appreciate the value of experimental studies, and to insist on proper laboratory accommodation being provided.

Surely the munificent donor will accept for his gallery some other site equally good for art, and not insist on striking a blow at science by taking a piece of land already set apart for laboratories.

HENRY E. ARMSTRONG,
Secretary of the Chemical Society.
W. E. AYRTON,
President of the Physical Society.

It seems probable that, as the discussion goes on, some side light will be thrown upon the motives of those who have the "munificent donor" in hand. Although we have not room for the whole of a letter from Mr. Marshall of Edinburgh, the general drift of it may be stated as follows:—

Mr. Marshall's main point is that, according to the statements made by Sir Frederick Leighton in his speech at the Royal Academy banquet, the new gallery is to be used as "a worthy home for the permanent display of the works of contemporary native artists"—which "means, being interpreted," says Mr. Marshall, "a worthy home for the works of Royal Academicians and their friends." The object for which Sir James Linton, Sir J.C. Robinson, Mr. Orrocks, and others have been contending is that there should be adequate "recognition throughout its whole range, both as regards masters and mediums of work, of the artistic triumphs of the masters of our English school." What these gentlemen have urged and incontestably proved is that while foreign art, and especially early Italian art, is fully if not excessively represented in our National Gallery, and while a few of our great native artists (notably Turner and Constable), and many of our small ones, are represented far beyond what is necessary or even desirable, our native water-colour art is practically not recognized at all, and many of the very greatest of our masters in oil, who were (most of them) masters in water-colour also—Cox, Miller, Barret, De Wint, Crome, Cotman, Stark, Vincent, and others—are either conspicuous by their absence, or miserably represented as regards quality or quantity or both. If the public wants a "permanent display of the works of contemporary native artists," and if a generous millionaire is willing to provide "a worthy home" for such productions, the thing can be done. "But I object," continues Mr. Marshall, "to our astute Academicians, with the accomplished President at their head, calmly stepping in and absorbing a movement at the very moment of its success, diverting it from its legitimate purpose, and, after having stoned the prophets of English art while they lived, now endeavouring to steal the stones that others have quarried and hewn for the martyrs' monument in order to erect with them another comfortable mansion for themselves." Mr. Marshall is of opinion that "provincials" have opportunities more than enough of seeing contemporary art. Their wish now is to have a chance of studying fine specimens, authoritatively selected, of the acknowledged masters of our English school.

The possible existence of such special motives as those here suggested among the persons who are attempting to get a grant of land for the carrying out of their so-called national objects should form an additional inducement to men of science to redouble their efforts.

NOTES.

THE general programme for the Cardiff meeting of the British Association has now been arranged. The first meeting will be held on Wednesday, August 19, at 8 p.m., when Sir Frederick Abel, K.C.B., will resign the chair, and Dr. William Huggins, President-elect, will assume the presidency and deliver an address. On Thursday evening, August 20, at 8 p.m., there will be a *soirée;* on Friday evening, August 21, at 8.30 p.m., a discourse on "Some Difficulties in the Life of Aquatic Insects," by Prof. L. C. Miall; on Monday evening, August 24, at 8.30 p.m., a discourse by Prof. T. E. Thorpe, F.R.S.; and on Tuesday evening, August 25, at 8 p.m., a *soirée.* On Wednesday, August 26, the concluding general meeting will be held at 2.30 p.m.

THE arrangements for the International Congress of Hygiene and Demography are nearly complete, and the programme, corrected up to May 1, has been issued in the form of a pamphlet. It has been definitely fixed that the opening meeting, at which the Prince of Wales is to preside, shall be held on Monday, August 10, at 3.30. The sections (of which there are ten) will meet on the four following days from 10 to 2. The six medical and scientific sections will meet in the rooms of the Royal and other learned Societies at Burlington House. The University of London will give the use of its large theatre to the section for the hygiene of infancy and childhood, and two examination halls to the sections for architecture and engineering. The division of demography will meet in the Theatre of the School of Mines, Jermyn Street. Much attention is being given to the necessary social preparations; and there is already a long list of proposed entertainments and excursions.

A GENERAL meeting of the Federated Institution of Mining Engineers will be held in London on Thursday, the 28th inst., at 12 noon, and on Friday, the 29th, at 10 a.m., in the rooms of the Institution of Civil Engineers, 25 Great George Street, Westminster. Various works will be visited on the 29th inst.

THE Committee of the Cardiff Naturalists' Society have put on foot a petition in favour of Mr. Pease's "Bill to Amend the Wild Birds' Protection Act, 1880." They are appealing to other scientific societies to join with them in order to make the petition as effective as possible.

AT Mowbray, a suburb of Cape Town, Mr. Cecil Rhodes has bought for £16,000 land on which, it is understood, the proposed University is to be built.

THE death of Prof. Carl Wilhelm von Nägeli, the eminent botanist, is announced. He died at Munich, on the 10th inst., in the 74th year of his age, and will be buried at Zürich, in accordance with a wish expressed before his death. Prof. von Nägeli was a Foreign Member of the Royal Society. We hope on a future occasion to give some account of his scientific labours.

THE Australian papers announce the death of Dr. Richard Schomburgk, brother of the late Sir Robert Schomburgk, and for many years Director of the Botanic Gardens at Adelaide, South Australia. Dr. Schomburgk was associated with his brother in the Boundary Demarcation Commission of British Guiana in 1840, and, some years later, settled with another brother in South Australia as a farmer and wine-grower. On the death of Mr. Francis, in 1866, he was offered, and accepted, the post of Director of the Adelaide Botanic Gardens, which he held with much distinction until his death. He was an enthusiastic horticulturist, rather than a botanist—that is to say, as an author; and his services in connection with the establishment he directed were very highly appreciated, as the sketches of his career testify. Indeed, so long ago as 1883, a large number of his admirers subscribed the funds to procure his portrait for the Museum of Economic Botany, founded by himself. His literary work commenced, we believe, with his "Reisen in Britisch Guiana in den Jahren 1840–1844," the third volume of which is devoted to a "Versuch einer Flora und Fauna von Britisch Guiana," in which Schomburgk had the assistance of several other botanists. This work has not yet been superseded, though its usefulness is unfortunately much limited by the publication of a large number of new names without descriptions. In 1876, Dr. Schomburgk supplemented this work by his "Botanical Reminiscences of British Guiana." But his most valuable literary work relates to the botany, to the agricultural and horticultural capabilities of his adopted country, and especially to the Botanic Garden, of which he was to a great extent the creator. His name will long be remembered in connection with this establishment, which is, it is asserted, the "most complete paradise of flowers in the southern hemisphere."

ACCORDING to the Calcutta correspondent of the *Times*, the Miranzai Expedition, under Sir W. Lockhart, has obtained much valuable geographical information about places which, although within a few miles of the frontier, have been hitherto unvisited by Europeans. The surveys effected by the Kuram field force during the Afghan war have been carried on to the Kurmana Valley.

A RUSSIAN scientific expedition, under the command of Captain Bartshevsky, has left Samarcand for the exploration of Southern Bokhara, the Pamir district, and Kafiristan.

ON Saturday, May 30, at the Royal Institution, Prof. A. H. Church, Professor of Chemistry in the Royal Academy of Arts, will begin a course of three lectures on the scientific study of decorative colour.

THE Rev. H. N. Hutchinson has undertaken to write for Messrs. Swan Sonnenschein and Co.'s "Introductory Science Text-books" a manual of physical geology. A second edition of Dr. Hatch's "Petrology" in the same series, reviewed in our columns last week, has already appeared.

MESSRS. WHITTAKER & Co. have in preparation a "Library of Popular Science." Among the works to be included in it are "Astronomy," by G. F. Chambers; "Light," by Sir H. Trueman Wood; "Chemistry," by T. Bolas; "Mineralogy," by Dr. F. H. Hatch; "Electricity and Magnetism," by S. Bottone; "Geology," by A. J. Jukes-Brown; "Botany," by G. Massee.

MR. J. ALLEN BROWN has expounded in the *West Middlesex Standard* an excellent scheme—now printed separately—for a technical institute and museum for the Ealing Parliamentary division of Middlesex. This division comprises Ealing, Acton, and Chiswick, and Mr. Brown's proposal is that a technical institute and museum should be established in whatever position may be most convenient for these localities. An essential part of his plan is that the instruction shall be imparted by specially qualified teachers and lecturers, and that their duties shall be "migratory or peripatetic," so that classes may be conducted or lectures given in any part of the division, and on any of the subjects contemplated under the Technical Instruction Acts. We commend Mr. Brown's scheme to the careful attention of the Middlesex County Council, which will soon have to decide as to the distribution of the funds placed at its disposal for technical instruction. There can be no doubt that the proposed institutions would be of immense advantage to the three districts, for Mr. Brown has a very enlightened conception of the true nature of technical instruction. What he wishes is that the young workman shall acquire "a knowledge of the scientific or artistic principles which are applicable to his trade or industry," and that by the development of his powers of observation and insight into the laws which govern all things "he may afterwards be enabled to effect improvements and excel to a greater extent than heretofore in the work he desires to accomplish."

THE Göttingen Society of Sciences has recently offered the following prize in physics for September 30, 1893:—From the researches of W. Röntgen and A. Kundt on variation of the optical properties of quartz in the electric field, there appears to be a close connection between the electro-optic phenomena and the elastic deformations which that piëzo-electric substance shows under the action of electrostatic forces. An extension of these inquiries to a series of piëzo-electric crystals with various properties of symmetry seems highly desirable. The investigation should also be directed to determining whether the electro-optic phenomena in piëzo-electric crystals are caused exclusively by the deformations occurring in the electric field or, besides, by a direct action of the electrostatic forces on the light-motion. Prize, £25.

THE German Society for the Encouragement of Industry offers the following (among other) prizes: (1) How far is the chemical composition of steel, and especially the amount of carbon present, a measure of the usefulness of cutting tools? Prize, a silver medal and £300; date, November 15, 1891. (2) A silver medal and £150 for the best chemical and physical investigation of the most common iron paints. Date, November 15, 1894. (3) A gold medal and £150 for the best work on the magnetism of iron. This should comprise a critical comparison of previous observations; also personal observations on steel and wrought iron bars of the most various chemical composition possible, examination being made both of the strength of temporary magnetization with absolutely measured and varying magnetizing force, and the strength of permanent magnetism and its durability with regard to temperature-changes and vibrations. Date, November 15, 1893. (4) Investigation of the trustworthiness of the usual methods of determining the carbon in iron. Prize, a silver medal and £150; date, November 15, 1892).

THE extraordinary collection of mummies, papyri, and other objects of antiquarian interest recovered last February at Deir-el-Bahari is now safely housed in the Ghizeh Museum. According to the Cairo correspondent of the *Times*, all the objects are in good condition, although some anxiety was caused by the protracted journey by boats from Luxor. The correspondent says that the mummies mostly belong to the 21st Dynasty, and, though styled Priests of Ammon, are supposed to be the corpses of generals and other official dignitaries who bore ecclesiastical besides other titles. The 163 mummies and the 75 papyri are not yet unrolled, and it is difficult to form an estimate of their archæological value, as many of the sarcophagi bear different names on the outer and inner casings, whilst others have the names usually inscribed on the outer casings intentionally effaced. M. Grébaut thinks that, owing to this circumstance and the magnitude of the collection, some time will be required before any important communications can be made to the scientific world.

A SERIES of experiments has been lately made by Herr Rubner (*Archiv für Hygiene*), with regard to the familiar fact that not only dry high temperatures are more easily borne than moist, but dry cold causes much less discomfort than moist cold. Dogs, fasting or fed, being observed in an air-calorimeter, it appeared that, in all cases, moist air increased the loss of heat by conduction and radiation. For every variation of the air-moisture 1 per cent., heat was parted with to the extent of 0·32 per cent. In a previous investigation, Herr Rubner demonstrated the lessened yield of water by evaporation from animals where the air-moisture is increased, involving lessened loss of heat. Here, then, are two antagonistic influences. He is disposed to regard the increased radiation and conduction in moist air as the primary action, and the diminished evaporation as secondary. The colder feeling of moist cold than dry is readily explained by the increased heat radiation. In moist heat, with the sense of oppression it brings, this factor passes rather into the background. The degree of temperature, and some other influences, of complex nature, also affect the amount of radiation.

THE Meteorological Council have issued a publication containing the hourly means obtained from the self-recording instruments at their observatories for the year 1887. This work constitutes a new departure in the use made of the records of the self-registering instruments, and one which we think will be of much practical use to meteorologists. The publication of the hourly observations *in extenso*, at the request of a number of scientific men, began with the year 1874, and was continued until 1880, in a lithographed form, and the daily means were added in 1879; from the year 1881 to 1886 they were issued in a printed form. The Council, after careful consideration, have now come to the conclusion that it is preferable, for a time at least, to publish mean values only; hitherto no hourly means had been published by the Office, but in the present work these have been grouped into five-day and other periods, in a convenient form for discussion, and the necessity for dealing with an excessive number of values has thereby been obviated, while many useful tables not included in the old series have been added. It is proposed to calculate the means similarly for earlier years, while the original records will be carefully preserved, and will be available, should they be needed, for any special research.

THE Annual Report of the Director of the Royal Alfred Observatory, Mauritius, for the year 1889 shows that the island has again enjoyed immunity from storms; the greatest hourly velocity of the wind was 31 miles. The almost total absence of tropical cyclones in the South Indian Ocean during the year is considered by Dr. Meldrum as another confirmation of the law that these cyclones are fewest in number and least intense in the years of least solar activity. The mean temperature was 0°·7 below the average for the last fifteen years, and below the average in every month except July and October. The maximum shade temperature was 93°·1 on March 27, and the minimum 52°·4 on June 18. The rainfall was 8·56 inches above the average; the greatest fall in one day was 3·88 inches on March 11, although this amount was much exceeded in other parts of the island. On January 1, a waterspout burst on the Pouce Mountain; Port Louis was flooded, and some persons were drowned. The collection of observations made at sea is actively carried on; 324 log-books were received, and the observations duly tabulated. The Report also contains observations made at the Seychelles and Rodriguez.

IN a paper recently published in the *Meteorologische Zeitschrift*, Prof. Hellmann, of Berlin, shows, from observations taken at different British, Continental, and American stations, at which barographs are used, that there exists a close coincidence in the daily range of the monthly extremes and in that of the hourly values of the barometer. He finds that the hours of occurrence of the highest and the lowest readings of the barometer during a month agree almost completely with the times in which the normal daily range has its maxima and minima, both curves being so similar in shape that it may be possible to judge of the general character of the daily range of the barometer from knowing only the hours at which the monthly extremes mostly occur. Hence, as the lowest readings of the barometer are accompanied by cloudy and stormy weather, during which the effect of the solar radiation upon the surface of the earth and the heating of the lower strata of the atmosphere are quite insignificant, Prof. Hellmann concludes that Prof. Hann and others are right in assuming that the normal daily range of the barometer is chiefly an effect of the *absorption of the solar rays in the upper strata* of our atmosphere. Prof. Hann has applied the harmonic analysis to the numbers furnished by Prof. Hellmann, and, by combining several stations in a group, has found the coefficients of the periodic formula to be practically the same as those for the normal daily range. We should, however, like to see a further confirmation with respect to the coincidence of the lowest readings and the diurnal minima, since the lowest readings occur so frequently during the passage of a severe storm, which can scarcely be said to have any agreement with the ordinary diurnal fluctuation.

The first paper in the last volume of Transactions of the Seismological Society of Japan is by Mr. Bertin, and describes the double oscillograph and its employment for the study of rolling and pitching. It traces curves automatically, showing the motion produced in a floating body by waves. The second paper is on the "Seiches" of lakes, by Dr. F. A. Forel, of Geneva, and discusses those variations in the level of the water of lakes with the investigation of which the author's name has been associated for some years past. Prof. John Milne describes the remarkable instrument invented by him for measuring and recording the oscillatory movements of railway trains. Mr. Mason contributes a paper, accompanied by carefully compiled tables, demonstrating the importance of elaborating some uniform system of timekeeping for the purposes of seismological observations. Prof. C. G. Knott, in his paper on earthquake frequency, explodes two of the time-honoured delusions of the popular mind in regard to earthquakes, viz. that they are more frequent during the night than the day, and that their periodicity is connected with lunar culminations. Mr. Otsuka gives an interesting account of the great earthquake that visited Kumamoto in July 1888; and Mr. Pereira contributes a carefully compiled record of all the earthquakes noted by him in Yokohama from March 1885 to December 1889. Mr. W. E. Forster writes on earthquakes of non-volcanic origin, caused, it is suggested, by the displacement of masses of land beneath the ocean. The volume concludes with various reports and papers by Prof. Milne, such as diagrams of earthquakes recorded in Tokio, a report on earthquake observations made in Japan during the year 1889, and an essay on the connection between earthquakes and electric and magnetic phenomena, which is full of matter of an interesting and suggestive kind.

According to the *Colonies and India*, Mr. Alexander McPhee, a West Australian bushman, who has steadily been earning fame lately by his explorations in the central regions of Australia, started inland from Roebourne in July last on another tour of discovery, taking back at the same time an albino aboriginal whom he found and brought to Melbourne a couple of years since. News has been received from which it appears that Mr. McPhee, with the albino, Jun Gun, and a "black fellow" named Timothy, went along the coast some 250 miles to a station called Yinadong, when the party turned inland in an easterly direction. After travelling about 350 miles, Mr. McPhee came upon another albino, a boy of fourteen years, whom he describes as the most extraordinary specimen of humanity he ever saw. One old man in this camp told Mr. McPhee that when he was a boy he heard of a party of whites and horses dying a long way inland. The old fellow could give no particulars about this party, but Mr. McPhee feels certain, owing to his acquaintance with the habits and customs of the blacks, and being thoroughly conversant with their dialect, that a party of white men perished about forty years ago somewhere in the interior. He heard of Warburton's party, and saw a native who told him that he guided them to water. He also heard of two parties of whites who had lately been in the desert, but turned back. From his turning point to the coast of La Grange Bay, Mr. McPhee reckons he was about 250 miles in a south-east direction from that bay. He found the natives very friendly, and on no occasion was it necessary to keep a watch. The country is described as very poor. The only birds observed during the journey were an odd crow and a few sparrows about the water; not a track of a kangaroo or emu was seen.

Some satisfactory statements as to the growth of collegiate education are made in the last official report on public instruction in the North-West Provinces and Oudh. Of individual colleges, Agra, at which the numbers in 1885 had fallen as low as 45, has increased within the last two years from 97 to 175, or by over 80 per cent., and the percentage of increase last year was in no case less than 20. The number of matriculated students, indeed, is rising so rapidly that the existing accommodation is said to be barely adequate; it will, the Government resolution says, become a question of urgent importance whether the increasing number of students should be provided for by additions to the staff and buildings at the colleges now in existence, or by the creation of new colleges, or by the strengthening of the college classes at high schools and adding to their number. "Government," it is added, "will necessarily be guided to a great extent by the nature and direction of the local demand, as indicated by the willingness of the residents of the principal towns to contribute to the increased burden of expenditure." On its present basis, at all events, the higher education of India has received a fair share of Government support. But if it is satisfactory, says the *Pioneer*, to find that collegiate education in its present form is making decided progress, and that it is becoming possible to throw the cost of the advance on private shoulders, it is a distinct disappointment that not a word is said, as not a step has been taken, in those new directions of educational activity where other provinces have not only started, but made appreciable progress. There may be two opinions as to the extent to which, or the means by which, it is possible to introduce technical education, but there can be no question that some movement is desirable. It may be hoped that the omission is due, not so much to a failure to estimate the importance of the subject, as to a desire to give it fuller treatment on a future occasion.

The amount of apparent flattening of the vault of the heavens Prof. Reimann has lately attempted to measure by noting the point which seems to bisect an arc extending from the zenith to the horizon. From 83 observations at Hirschberg he found that this point was 21°·47 ± 0·08 above the horizon. This indicates a ratio of the vertical axis to the horizontal of 1 : 3·66. This apparent flattening has an annual period, and is dependent on cloud. The highest position of the bisecting point was assigned in autumn (21°·98), the lowest in spring (20°·42). The vault seems flatter the more the cloud. It seems least flat with a misty horizon; and the flattening seems less by night than by day. Curiously, several other persons whom Prof. Reimann got to make the same determination all gave higher values for the angle.

The settlement of a purely philological question (that, namely, as to the position of the French accent), by a physical method, has been recently attempted by Dr. Pringsheim, of Berlin (*Naturw. Rdsch.*) The instrument used was König and Scott's phonautograph, into which a number of Frenchmen were required to speak; the measurement of the record being afterwards made by means of a tuning-fork curve running parallel with it. This instrument renders possible a determination of the duration, pitch, and intensity of each syllable, and Dr. Pringsheim discusses its indications. As a preliminary result, he finds that two-syllable words have the vowels pronounced with equal length and strength. Noteworthy differences appear in the curve of a word according as it occurs in the middle or at the end of a sentence. In the latter case, there is added to the characteristic word curve, a terminal curve with declining pitch and strength, which is nearly the same for different words, and corresponds to the sinking of the voice before a pause. The vowels and consonants show characteristic curves; and notably long wave-lengths occur with *n*, *l*, *b*, and *d*. The duration of syllables varies between 0·1 and 0·5 second; and between the syllables of a word there are often pauses of 0·03 to 0·2 second. The shortest syllable *é* in *été*, with rather slow pronunciation, consisted of 22 vibrations; yet the ear is capable of not only hearing the tone, but of detecting fine shades and differences in the mode of pronunciation. Further experiments in this direction, with an improved apparatus, are contemplated.

THE *Perak Government Gazette* states that a portion of an ethnographical collection formed by Signor G. B. Cerruti, in the island of Nias, has been recently acquired by the Government of Perak for the museum. Pulo Nias is one of a chain of islands bordering the south-western coast of Sumatra. The population is said to be numerous and of one race, though divided into many tribes under independent chiefs. Head-hunting is as common with them as it used to be in Borneo, and most of the houses have skulls hung up in them. Their weapons consist of iron-headed spears, mostly barbed, knives of two patterns, somewhat resembling the Kadubong Achi, with shields of two distinct types. No bows and arrows or blow-pipes seem to be known, nor are throwing sticks applied to their spears; boats also are not used by them, though rafts are sometimes made to cross the rivers on. The ironwork of their weapons is fashioned by themselves, and the upright double cylinder bellows is used to supply wind to their forges—the same in every respect as those used by the Semangs of Upper Perak, and the far away Malagasy. Helmets of black ijoh fibre are worn, somewhat similar to the cocoa-nut fibre ones of the Sandwich Islanders. Woven body armour is in use, in the shape of thick coats made of what appears to be the fibre of *Hibiscus tiliacens*. Buffalo hide armour is also said to be used, but is not represented in this collection. Attached to the sheaths of some of the knives are four or five animals' teeth, such as tigers, rhinoceros, &c., also a small carved wooden idol, and one or more bamboo boxes containing stones. In those examined there were twelve pebbles in each box. These stones are supposed to have been taken from the spot on which a man had been slain. All these charms are tied up into a bundle with red cloth, and bound with string on the upper front part of the sheath of the knife.

A COMPREHENSIVE study of the influence of forests on the daily variation of air-temperature has been recently made by Prof. Müttrich (*Met. Zeits.*), the data being from stations in Germany and Austria. *Inter alia*, this influence is greater in May to September or October than in the other months. In pine and fir woods it rises gradually from January to a maximum in August or September, then falls more quickly to a minimum in December; but in beech woods a minimum occurs in April, then there is quick rise, till the maximum is reached in July. The daily variation itself is greatest in May or June, both in forest and open country. The influence of the forest is to lower the maxima and raise the minima, and the former influence is in most months greater than the latter; in December and January, and occasionally in neighbouring months, it is less. The influence on the maxima in summer is greatest in beech woods, less in pine, and least in fir. The absolute value of the influence in woods of a given kind of tree is affected by the degree of density of the wood, being higher the denser the wood. The character of the climate (oceanic or continental) also affects the results. From daily observations in forest and open country, every two hours in the second half of June, it appears that, soon after 5 a.m. and 8 p.m., the air-temperature in the wood was equal to that in the open; that the maximum was about 0°·9 lower in the wood, and the minimum 0°·6 higher; that in May to September the difference sometimes reached 2°·7; that the maximum in the wood occurred about half an hour later, and the minimum a quarter of an hour earlier, than in the open; and that the daily mean air-temperature was about ⅛° less in the wood.

THE *Revue des Sciences Naturelles de l'Ouest* gives an account of the life of Mathurin Rouault, one of the pioneers in the geology of Brittany. Rouault was born in 1813, of a very poor family. At the age of ten, while engaged as a shepherd, he became interested in "stones" and "rocks," and began to make a collection. By the death of a relative he obtained possession of a small hairdresser's shop, where he worked on Saturdays and Sundays, spending the rest of his time in hunting for rocks. Although Geoffroy Saint-Hilaire visited his collection of specimens, and was much interested in them, nothing would have been done for the poor young geologist—who lived upon something like five centimes a day—if it had not been for General de Tournemine, who, stationed with the garrison in Rennes, had been attracted by him. It is said that one day he went into the shop, and, seeing an antique pistol which Rouault had bought for a few centimes to kill himself with, the general remarked, "That is just the pistol I am after: I want it for my collection." And without waiting for an answer he took the pistol, and gave the young man 100 francs. M. de Tournemine went still further. He revised a memoir which the illiterate geologist had written. This was read in the Academy of Sciences, and met with so much success that the author became well known. The town of Rennes gave him 800 francs a year to help him to live in Paris, and afterwards he was appointed Director of the Geological Museum of Rennes. But he was dismissed on account of quarrels with some unintelligent bureaucrat, and died in 1881. Before his time only five or six fossils were known in Brittany: afterwards they numbered 500 or 600. He spent two years or more in making up *Trinucleus Pongerardi* out of over 2000 fragments.

AN important paper upon the atomic weight and position in the periodic system of the rare element lanthanum is contributed by Dr. Brauner, of Prague, late of the Owens College, Manchester, to the current number of the *Berichte*. In his recent work upon the reduction of oxides by metallic magnesium Prof. Winkler advanced the view that lanthanum is a tetravalent element of atomic weight 180, instead of, as has hitherto been accepted, a trivalent element belonging to the boron vertical group of the periodic system, with an atomic weight of 138·5. If lanthanum were indeed tetravalent with atomic weight 180, it would probably be the missing element between ytterbium and tantalum on the one hand, and cerium and thorium on the other. Further, Prof. Winkler expresses the opinion that the old values of Rammelsberg, Zschiesche, and Erk, for the equivalent of lanthanum, are correct. These experimenters obtained the round number 45 for the equivalent, and this number multiplied by 4 gives Prof. Winkler's suggested atomic weight 180. If, however, multiplied by 3, the atomic weight 135 is arrived at, and Prof. Winkler argues that even if the element were trivalent its atomic weight would not be 138·5 but 135. Against these views Dr. Brauner brings forward the following experimental facts. In the first place, Hillebrand (working under Bunsen) found the specific heat of Bunsen's pure lanthanum to be 0·04475. No impeachment has ever been brought against this result, and Dr. Brauner sees no reason why it should not be accepted. Making use of Dulong and Petit's generalization and multiplying this number by 138, a normal atomic heat of 6·18 is arrived at, whereas if multiplied by 180 the abnormal value 8·07 is obtained. Again, an element of atomic weight 180 should possess a density of 8·2, whereas that of lanthanum is only 6·48, a specific gravity corresponding to an atomic weight of 138. Considering therefore the position of lanthanum in the trivalent boron vertical group assured, Dr. Brauner brings forward a redetermination of its atomic weight of his own in order to decide between 138·5 and 135. His experimental method consisted in converting known weights of the oxide into sulphate. The material employed was obtained by a lengthy process of fractionation with ammonium nitrate, the oxide eventually obtained containing the most positive of the cerite earths (lanthanum oxide) and showing no traces in the spectrum of any others. His value thus obtained is 138·2, a number closely agreeing with those of Cleve and Bettendorff. The earlier and lower values of Rammelsberg and others are shown to be probably due to the presence of yttria, which was not detected by these observers, inasmuch as the work of Thalén and Bunsen upon the spectrum of yttrium had not then been published. Hence lanthanum of atomic weight 138·2 retains the place in the trivalent group of the periodic system marked out for it by its well-known basic properties.

THE additions to the Zoological Society's Gardens during the past week include a Striped Hyæna (*Hyæna striata* ♀) from India, presented by Mr. B. T. Ffinch, C.M.Z.S.; two Hairy-rumped Agoutis (*Dasyprocta prymnolopha*) from British Guiana, presented by Mr. H. Barrington; two Brent Geese (*Bernicla brenta*), a Pintail (*Dafila acuta* ♂), two Wigeons (*Mareca penelope* ♂ ♀), a Common Sheldrake (*Tadorna vulpanser* ♀), two Golden Tench (*Tinca vulgaris*, var.), nine Golden Carp (*Carassius auratus*), British, presented by Mrs. Atkinson; eight European Tree Frogs (*Hyla arborea*) from the South of France, presented by Mr. Clifford D. Fothergill; a Crested Porcupine (*Hystrix cristata*) from India, a Tibetan Crossoptilon (*Crossoptilon tibetanum* ♀) from Western China, deposited; two Swinhoe's Pheasants (*Euplocamus swinhoii* ♂ ♀) from Formosa, two Japanese Pheasants (*Phasianus versicolor* ♀ ♀) from Japan, two Amherst's Pheasants (*Thaumalea amherstiæ* ♀ ♀) from Szechuen, China, a Black-necked Stilt Plover (*Himantopus nigricollis*), a Cayenne Lapwing (*Vanellus cayennensis*) from South America, purchased; a Wild Swine (*Sus scrofa* ♀) from Persia, received in exchange; two Indian Desert Foxes (*Canis leucopus*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE PHOTOGRAPHY OF FAINT NEBULÆ.—In the Journal of the British Astronomical Association for February, Dr. Max Wolf, of Heidelberg Observatory, contributes a note on a nebula surrounding ζ Orionis, the third star in the belt, which he has discovered on photographs taken with a 4-inch portrait lens. Some reproductions submitted to the Association show a large amount of nebulosity south-west of ζ, also nebulous ground around ζ, and a nebulous star north of ζ. Dr. Wolf's note is important, inasmuch as it indicates that the 4-inch portrait lens used at Heidelberg gives results which compare favourably with those obtained at Harvard with a much larger instrument, viz. the Bache equatorial of 8 inches aperture and 44 inches focal length. With regard to the use of portrait lenses for celestial photography, Dr. Wolf makes a few succinct remarks. In photographing the stars, the intensity of the image depends only upon the area of the lens employed, and an instrument of 20 inches diameter therefore requires 25 times less exposure than one 4 inches in diameter having the same focal length, in order to obtain the same number of stellar images. But it is a different thing with comets, nebulæ, and the like—bodies having a finite area. The intensity of the image at the focus then varies as the fraction $\left(\frac{d}{f}\right)^2$, where d is the diameter of the object-glass, and f its focal length. If, therefore, the intensity of the light received with an aperture of 20 inches and focal length of 100 inches be expressed by 0·04, that of a portrait lens of 4 inches aperture and 12 inches focus is 0·11. This shows that in order to photograph the same faint nebula, the instrument of 20 inches aperture requires an exposure about three times as long as the 4-inch portrait lens.

Another paper having the same purport is contributed by Dr. Holden to vol. iii. No. 14, of the Publications of the Astronomical Society of the Pacific, from which it appears that from 80 to 100 minutes' exposure with the 33-inch Lick telescope will give about the same number of stars as 205 minutes' exposure with Mr. Roberts's 20-inch reflector. When, however, the amount of nebulosity depicted is considered, the advantage is considerably in favour of the short-focus reflector, a comparison of the results obtained with the two instruments indicating that 15 minutes' exposure with the reflector is about as effective in showing the nebulosity of Orion as 60 minutes' with the refractor.

VARIATIONS IN LATITUDE.—Prof. H. G. van de Sande Bakhuyzen extends our knowledge of this subject in a paper contained in the March number of the *Monthly Notices* of the Royal Astronomical Society. The conclusions deduced from the investigation of observations of Polaris made between 1851 and 1882, and the interesting researches of Mr. Thackeray (Memoirs R.A.S., vol. xlix. p. 239), may be summed up as follows:—(1) The monthly discordances in the zenith distances of Polaris are, for the greater part, not caused by a real variation of latitude, but chiefly by an effect of temperature. (2) It is not possible to explain those discordances by an error in the indications of the exterior thermometer, or by an influence depending only on the exterior temperature. (3) The discordances can be explained, for the greater part, by a cause depending on the difference of the exterior and interior temperatures. (4) Probably that cause is a refraction in the observing-room, and its effects are sensibly proportional to those differences of temperature. (5) The discordances corrected for that refraction are about the same for both culminations, and can be explained by a real variation of latitude.

An investigation of the mean North Polar distances of Polaris in both culminations observed at Greenwich between 1883 and 1889 leads to the conclusions: (1) that it is probable that the observations of Polaris at Greenwich confirm the variations of latitude observed elsewhere in 1884–1885 and 1889–1890; (2) that there is a very strong probability that the variations in these years had an exceptional character, and do not agree with the annual variations, deduced from the observations of Polaris at Greenwich during the period 1851–1882.

RE-DISCOVERY OF WOLF'S COMET (1884 III.).—*Astronomische Nachrichten*, No. 3033, contains the information that Wolf's periodical comet was observed on its return by Prof. Barnard, of Lick Observatory, on May 3·9792 G.M.T. The following ephemeris is from one given in *Edinburgh Circular* No. 15, by Prof. Berberich. The brightness of the comet at re-discovery has been taken as unity.

Ephemeris for Berlin Midnight.

1891.	Right Ascension.			Declination.		Brightness.

The comet will pass perihelion on September 3·3199 Berlin mean time. It is near α Pegasi at the present time, and may therefore be seen just before sunrise. The motion is towards Andromeda.

THE PARIS OBSERVATORY.[1]

THIS report opens with the address delivered by the Director, Admiral Mouchez, before the Council of the Observatory on February 24 last; the following is a brief summary of the most important points touched upon.

After referring to the successful completion of the building for the large *equatorial coudé*, in which the instrument is now being erected, and to the formation of a special service for spectroscopy, over which M. Deslandres has been put in charge, he enters on the question of the formation of a branch establishment outside Paris. "The demands of modern science," he says, "the extreme smallness of the quantities on which the astronomy of position depends, and the extreme faintness of the objects that physical astronomy studies in order to penetrate more and more deeply into the knowledge of the universe, admit indeed of new processes of observation of such delicacy that they are altogether incompatible with the turmoil and disturbances of all kinds in a populous city. The instruments with large optical power lose nearly all their superiority, because they magnify the defects of an impure and disturbed atmosphere at least as rapidly as the images of the stars."

This is by no means the first time that this question of a branch establishment has been raised, but it looks very much as if it might now be taken up seriously. It seems that a proposal has been made to extend the railroad from Sceaux-Limours in the interior of Paris to Médicis and Cluny, where it would join the metropolitan; if this project was carried out, trains would run as close to the Observatory as 150 metres, thus affording the assistants at the Observatory an interesting amusement in calculating the distances of these trains by the vibrations set up in the various instruments.

A committee of inquiry, presided over by M. Chauchat, has been formed to inquire into the situation, and the unanimous opinion of all the astronomers questioned on the subject was that "the Observatory would be almost lost if this project was carried out according to the present conditions."

Of the other arguments put forward by Admiral Mouchez in favour of the branch establishment, the following may be mentioned. The lighting of the surrounding streets by means of the electric light. This, as he says, would obliterate all stars above the 12th magnitude, and perhaps even above the 11½th, to say nothing of the minor planets, nebulæ, and some comets. And with regard to photographing the heavens with moderate exposures, it would become nearly impossible owing to the fogging of the plates before the images are formed, the gas from the street lamps even now producing this effect on the sensitized plates. Referring to the opening and enlarging of the Rue Cassini, he points out, that at no remote date, houses will be constructed from 20 metres to 25 metres in height at a distance of 100 metres, and just in the direction of the meridian line of the instruments; these, besides completely blotting out from view many of the circumpolar stars at their lower culmination, will render the observation of those that remain difficult on account of the smoke from the chimneys.

Following Admiral Mouchez's address are the reports, from each of the heads of the various departments, of the work done during the past year. With the meridian circle no less than 14,374 stars have been observed, exclusive of the 432 observations of the planets made with the same instrument. Observations which were commenced in the month of April with the *equatorial coudé*, have been regularly pursued, and at present the results have been highly satisfactory. Not only "do we believe that we have settled in every detail the most precise rules for the application of the new method, but also we have obtained the constant of aberration with an exactness which surpasses all researches made up to the present time."

The three equatorials have been used by M. Bigourdan, Mdlle. Klumpke, and M. Boinot respectively, and with them observations have been made of comets, double stars, nebulæ, eclipses of Jupiter's satellites, occultations, planets, and double stars.

M. Paul Henry, who is chief of the photographic department, has been busily engaged among other things in making large *clichés* of different regions of the sky, several of which were prepared at the request of foreign astronomers.

The most important addition to the Observatory for the year was the special service for stellar spectroscopy, which, as we have mentioned before, is superintended by M. Deslandres. This branch, when in full working order, should be of the utmost value to science, and the results obtained will be looked forward to with interest. With regard to this branch Admiral Mouchez has given an extract from M. Deslandres' report on the installation of the apparatus and the results obtained.

After a short description of the meteorological work carried on, together with the various other reports usually inserted in this pamphlet, Admiral Mouchez concludes with a brief reference to the Observatory School at Montsouris, of which also he is Director. This school was organized under the patronage of the Bureau of Longitudes, in order to supply a want long felt in France of a school for practical astronomy, where "marine officers, explorers, professors of science, and others could come and accustom themselves to make observations." Since the year 1877 the Observatory has been freely opened to anyone, the only conditions being that those who go should have sufficient scientific knowledge to understand what is taught, and that their work should be regular. To give an idea of the range of the subjects that form the syllabus of instruction we cannot do better than condense the methods of organization as given in the report.

With regard to astronomy, both theoretical and practical lectures are given twice or three times a week. M. Boitel delivers a course on electricity and magnetism which extends over four months, during which time he conducts the officers over all the large electrical manufactories in Paris. Lectures on meteorology are delivered by M. Moureaux, who concludes them with practical instructions for the determination of the magnetic elements. M. Thoulet treats of ocean geography in a course that is of interest and use to sailors. The regulation of the compass, so important to-day on account of our iron ships, forms the subject of a number of lectures by M. Caspari, while photography is studied for two months under the superintendence of M. Guenaire.

From this syllabus it will be seen that a good, practical, and sound course is open to all those who wish to take advantage of it, and in the list of explorers who have figured in the principal missions during the last fifteen years the majority will be found to have served at any rate a short period at the Observatory School.

In concluding his remarks, Admiral Mouchez, after referring to the school that was started in 1879, and which was suppressed some years after for reasons of economy, points out the necessity of giving every encouragement to the one that is doing such good work at Montsouris.

W. J. L.

NOTE ON THE PHYSIOLOGICAL ACTION OF CARBON-MONOXIDE OF NICKEL [$Ni(CO)_4$].[1]

BY the kindness of Mr. Ludwig Mond, we have had the opportunity of examining the physiological action of carbon-monoxide of nickel, a substance of unique chemical composition, represented by the formula $Ni(CO)_4$. The general results of our investigation are as follows:—

(1) $Ni(CO)_4$ is a powerful poison when injected subcutaneously into a rabbit weighing 1·5 kilo. even with a dose of 1/30th c.cm.

(2) The vapour of $Ni(CO)_4$ in air, even to the extent of 0·5 per cent., is dangerous.

(3) The symptoms are those of a respiratory poison, and are similar to those caused by carbonic oxide.

(4) The spectrum of the blood of an animal poisoned by $Ni(CO)_4$ is that of carbonic-oxide-hæmoglobin, and it is not reduced by sulphide of ammonium.

(5) When the substance is injected subcutaneously it is probably in part dissociated in the tissues, as there is evidence of the existence of nickel in those tissues, but the nickel also finds its way into the blood, and is found there.

(6) The substance produces a remarkably prolonged fall of temperature even when given in small quantities. In several instances, with lethal doses, the fall was from 2° to 12° C. This may be accounted for by the hæmoglobin being prevented to a large extent from supplying the tissues with oxygen. Nico, as we may, for convenience, call this substance, makes it possible to give graduated doses of carbonic oxide, and thus reduce temperature

---

[1] By John G. McKendrick, M.D., F.R.S., and William Snodgrass, M.A. M.B., Physiological Laboratory, University of Glasgow.

by directly interfering with the respiratory exchanges occurring in the tissues. The objections to its use as an antipyretic are that, owing to its poisonous properties, it is difficult to inject it subcutaneously in sufficiently small doses, while it is not easy to obtain a solution in any menstruum in which decomposition will not take place. If a convenient method of dissolving it could be devised, $Ni(CO)_4$ might become a valuable antipyretic, the *modus operandi* of which is intelligible.[1]

SOCIETIES AND ACADEMIES.

LONDON.

Chemical Society, April 2.—Mr. W. Crookes, F.R.S., Vice-President, in the chair.—The following papers were read:—Citraconfluorescein, by J. T. Hewitt. Lunge and Burckhardt have shown that maleic anhydride is capable of yielding a fluorescein; the author has obtained the corresponding fluorescein from citraconic anhydride, by the action of resorcinol in the presence of sulphuric acid. Citraconfluorescein is easily soluble in alcohol and glacial acetic acid, fairly soluble in water; the aqueous solution is yellowish-brown and shows a green fluorescence.—Ethylic thiacetacetate, by Dr. C. T. Sprague. Hübner obtained ethylic thiacetacetate by the action of sulphur monochloride, S_2Cl_2, on ethylic acetacetate. It has since been obtained by Delisle by the action of sulphur dichloride, SCl_2, on ethylic acetacetate; by Schönbrodt by the action of sulphur on the copper derivative of ethylic acetacetate; and by Michaelis and Phillips from thionyl chloride and ethylic acetacetate. Buchka proposed the formula $S(CH.Ac.CO_2Et)_2$, but an alternative formula, $S(O.C:CH.CO_2Et)_2$, was suggested by Delisle. The author describes the preparation of the substance and the products of its interaction with hydrazines; and shows that it behaves towards phenylhydrazine in the same manner as ethylic acetacetate. The results are in accordance with the formula proposed by Buchka.—The function of chlorine in acid chlorides as exemplified by sulphuryl chloride, by H. E. Armstrong. A number of experiments carried out during recent years in the author's laboratory show that sulphuryl chloride, SO_2Cl_2, acts on benzenoid compounds simply as a chlorinating agent. Sulphuryl chloride is easily formed by the direct union of sulphur dioxide and chlorine in the presence of a catalyst, such as camphor, charcoal, or acetic acid; it is a highly mobile liquid of low boiling-point, and is acted on with extreme slowness by water and alkaline solutions. It is an inert substance possessed of properties by no means such as are usually regarded as characteristic of acid chlorides. The chlorine is apparently but loosely held, and is easily withdrawn by a compound having an affinity for chlorine, such as naphthalene. On warming a mixture of this hydrocarbon and sulphuryl chloride, SO_2 is evolved and naphthalene tetrachloride is produced. The author doubts whether the chlorine in acid chlorides is possessed of special activity, and is inclined to the view that the activity of acid chlorides is conditioned by the oxygen rather than the chlorine; this view being supported by the observations of Wagner and Saytzeff, and the later ones of Pawlow (*Annalen*, clxxxviii. 104). The author also discusses the action of SO_3HCl, and the analogous compound $SO_3.EtCl$, and points out that pyrosulphuryl chloride, $S_2O_5Cl_2$, behaves much as if it consisted of SO_3 and SO_2Cl_2.—The action of nitric acid on the ligno-celluloses, by C. F. Cross and E. J. Bevan. Dilute nitric acid attacks the ligno-celluloses when heated with them at 60°, with the formation of a bright yellow derivative of lignone and nitrous acid On further interaction, large quantities of nitrous oxide, N_2O, are evolved, together with carbonic anhydride and a small proportion of nitric oxide. A sensible quantity of hydrogen cyanide is also produced, the proportion being increased by increase of temperature. The observations point to the entrance of the NOH residue into the lignone molecule; its interaction with nitrous acid being finally the displacement of H_2 by O. The reaction is probably general for compounds containing the NOH residue, and the authors suggest that attention be paid to the gaseous products of the interaction of nitric acid and carbon compounds, as calculated to elucidate their mechanism.—The Chairman, Mr. Crookes, gave a short verbal account of observations on the volatilization of metals *in vacuo* under the influence of an electric discharge.

April 16.—Prof. A. Crum Brown, F.R.S., President, in the chair.—The following papers were read:—Studies on the formation of substitution derivatives, by H. Gordon. The following experiments were undertaken with the object of throwing further light on the laws which govern substitution in the case of benzenoid compounds. *The action of bromine on diorthonitrophenol.*—When bromine is added to an acetic acid solution of diorthonitrophenol at ordinary temperatures, the normal product, namely parabromdiorthonitrophenol, is obtained. However, if the mixture be heated at 100° for a short time, a mixture is obtained consisting of parabromdiorthonitrophenol and orthobromorthoparadinitrophenol. And if the heating be prolonged, and small quantities of bromine added, the mixed product is converted into orthobromorthoparadinitrophenol. Parabromdiorthonitrophenol is therefore completely converted by the action of heat, and bromine into the isomeric orthobromorthoparadinitrophenol. The same isomeric change takes place under the influence of nitric acid. An acetic acid solution of parabromdiorthonitrophenol, when heated with a few drops of nitric acid at 100°, is completely converted into the isomeric orthobromorthoparadinitrophenol. Experiments were then undertaken with the corresponding chloro-compounds. It was found that chlorine had no action on diorthonitrophenol when dissolved in acetic acid at 100°, even in the presence of iodine. Chlorination, however, takes place when chlorine is passed into a solution of diorthonitrophenol in antimony pentachloride at 105°, and only the normal product parachlorodinitrophenol is formed. *Action of bromine on parachlordiorthonitrophenol.*—Experiments to ascertain whether isomeric change could be effected by the action of bromine on parachlordinitrophenol only gave negative results, the normal product, parachlororthobromorthonitrophenol, being obtained in every case. The author considers that in the case of the chlorine compound isomeric change does not take place, because the chlorine is more firmly held than bromine. *Action of sulphuric acid on orthoparadichlorphenolorthosulphonic acid.*—The combined action of heat and sulphuric acid on orthoparadichlorphenolsulphonic acid gave no indication of any isomeric change taking place, although the reaction was investigated under a great variety of conditions of temperature, &c. The corresponding dibromphenol also gave negative results, but as several secondary reactions set in, such as the formation of tribromphenol, this reaction was not further investigated. *The chlorination and bromination of phenol.*—Phenol when chlorinated in the ordinary manner yields a mixture of para- and ortho- chlorphenol. The author finds that a similar mixture is obtained when SO_2Cl_2 is employed as the chlorinating agent. He has also investigated the action of bromine on phenol under the conditions described by Hübner and Brenken (*Ber.* vi. 170), and finds that the product is practically pure parabromphenol. *The sulphonation of the nitrophenols.*—Orthonitrophenol and paranitrophenol are, according to Armstrong, both readily acted upon by SO_3HCl; the former yields the well-known sulpho-acid; the latter yields a product which is decomposed by water, and was supposed by Armstrong to be the sulphate, and this the author finds to be the case. The author considers that the initial action in both cases is the same; but that the sulphate formed from orthonitrophenol at once undergoes isomeric change, whereas the sulphate from paranitrophenol is more stable. The author did not succeed in obtaining any sulpho-acid by heating the sulphate from the paranitrophenol at 100°. But he obtained a fair yield of sulpho-acid by heating the nitrophenol with two molecular proportions of SO_3HCl at 100°. Hence, there is little doubt that the paranitrophenolsulphonic acid is formed by the sulphonation of the sulphate. Metanitrophenol resembles the para-compound in being converted into sulphate, but not into the sulpho-acid even by the action of heat.—Compounds of dextrose with the oxides of nickel, chromium, and iron, by A. C. Chapman. The nickel compound is obtained by adding a solution of nickel hydrate in ammonia to a solution of dextrose in 90 per cent. alcohol. It is a green amorphous substance, insoluble in water and alcohol, of the composition $C_6H_{12}O_6.2NiO + 3H_2O$. The chromium compound, which appears to have the composition represented by the formula $C_6H_{12}O_6.Cr_2O_3 + 4H_2O$, is prepared by dissolving an excess of dextrose in an aqueous solution of chromic chloride, and pouring this solution into cold strong ammonia. The precipitated hydrate partly dissolves on standing, and on pouring the purple solution so obtained into 90 per cent. alcohol, the chromium dextrosate is obtained as a lilac-coloured precipitate. The iron compound, $2C_6H_{12}O_6.3Fe_2O_3$

---

[1] This investigation was carried on during last winter. It appears that M. Hanriot made a communication of the subject to the Société Chimique on February 27. He found the substance to be more poisonous than CO, and that the blood gave the spectrum of carbon-monoxide-hæmoglobin.

$+ 3H_2O$, is obtained by adding a slight excess of ammonia to a solution of ferric chloride containing an excess of dextrose; on standing, a deep red solution is obtained, which when poured into 90 per cent. alcohol yields the dextrosate of iron as a red flocculent precipitate. The moist compound dissolves easily in water to a red solution, is decomposed on boiling, but is not decomposed by ammonia, potassic ferrocyanide, or potassic thiocyanate. The dry compound is insoluble in water.—A rapid method of estimating nitrates in potable waters, by Dr. G. Harrow. The method depends on the reduction of nitric to nitrous acid by means of zinc dust and hydrochloric acid, in a very dilute solution, in the presence of α-naphthylamine and sulphuric acid; the estimation is made by comparing the depths of the pink azo-coloration developed in the solution with that arising on similar treatment of standard nitrate solutions. When nitrites are present, the amount is estimated in a similar manner prior to the addition of zinc dust, and due allowance is subsequently made. A number of comparisons with the Crum method show that very satisfactory results are obtainable. —The "gravivolumeter," an instrument by means of which the observed volume of a single gas gives directly the weight of the gas: a preliminary note, by F. R. Japp, F.R.S. The author describes a method of constructing a gas apparatus, by means of which, with an ordinary graduation in cubic centimetres, any required single gas may, without observation of temperature or pressure and without calculation, be measured under such conditions that each cubic centimetre represents a milligram of the gas. The author describes the apparatus in detail and the method of using it, and he anticipates that it will, at least, give results sufficiently accurate for technical purposes.—Mr. de Mosenthal exhibited one of Lipmann's coloured photographic negatives.—The action of acetic acid on phenylthiocarbimide, by J. C. Cain and Dr. J. B. Cohen, Owens College. The authors show that the product of the action of pure glacial acetic acid on phenylthiocarbimide is not diacetanilide, as stated by Hofmann; but that two compounds are formed—namely, diphenylurea and acetanilide. At low temperatures diphenylurea is mainly formed, at higher temperatures acetanilide. The reactions may be expressed by the following equations:—

$$2C_6H_5NCS + 6C_2H_4O_2 = (C_6H_5NH)_2CO + 3(C_2H_3O)_2{\cdot}O + 2H_2S + CO_2$$

and

$$(C_6H_5NH)_2CO + 2C_2H_4O_2 = 2C_6H_5NH_2 + (C_2H_3O)_2O + CO_2.$$

—The action of aluminium chloride on benzenoid acid chlorides, by R. E. Hughes, Jesus College, Oxford. The author has examined the action of aluminium chloride on cinnamic and hydrocinnamic chlorides, in the expectation that pentamethylene derivatives might result. The experiments, however, afforded negative results. The chloride was either dissolved in or mixed with light petroleum, and aluminium chloride then added; action set in at 80–90° in the case of cinnamic, and at 50° and more briskly in the case of hydrocinnamic, chloride. The chief product in both cases was an ill-characterized substance, which has not been examined. The author also describes the following compounds: hydrocinnamic chloride, hydrocinnamide, and hydrocinnamanilide. It is noted that benzoic and cinnamic acids may be readily separated by treating the mixture with phosphorus pentachloride and distilling the product under reduced pressure; the portion passing over below 95° under 10 mm. contains the benzoic chloride.

Amsterdam.

Royal Academy of Sciences, April 24.—Prof. van de Sande Bakhuyzen in the chair.—Mr. van der Waals dealt with a formula for electrolytic dissociation, which may be deduced from his theory of a mixture. This formula accounts for the facts (1) that ions may combine with absorption of heat; (2) that the parameter of electrolytic dissociation varies with the medium which holds the salt-molecules in solution; (3) that the quantity of free ions may diminish when the quantity of salt-molecules increases.

MEDICAL RESEARCH AT EDINBURGH.

Laboratory Reports of the Royal College of Physicians of Edinburgh. Vol. III. (Edinburgh and London: Young J. Pentland, 1891.)

NOW that for three years the laboratory of the Edinburgh Royal College of Physicians has shown steady advancement in every direction—in the number of workers engaged within it, in the volume of work accomplished, and more especially in the quality of that work—Dr. Grainger Stewart and his Council must congratulate themselves heartily that they were undeterred by any misgivings from entering upon a venture which has been so abundantly successful, and which has added so much to the renown of the College. It must be a source of very sincere satisfaction to them, and especially to Dr. Batty Tuke, the prime mover in its organization, to know that no laboratory in the Kingdom can show for the same space of time a record of so much good work in so many directions, of which a large part would never have been undertaken had this laboratory not been established.

In many respects the present volume exhibits marked improvement as compared with its predecessors. While composed of more than a dozen papers, these only represent but a portion of the investigations that have been completed, and all of them contain matter of permanent interest; others whose interest is of a more temporary nature have, I think wisely, been excluded. The value of the volume is further enhanced greatly by the fact that the majority of the reports appear here for the first time. Among these may be mentioned Dr. Helme's important contribution to the physiology of the uterus; Dr. Gulland's heterodox papers upon leucocytes and adenoid tissue; Noël Paton and Balfour's very full studies upon the composition and physiological action of the human bile; Woodhead and Cartwright Wood's observations upon bacterio-therapeutics; and a short but important communication by Cartwright Wood and Maxwell Ross on the influence which the process of inflammation exerts upon the course of infectious disease.

Taking these in order, Dr. Helme's paper is of especial value, not only clinically, from the light it throws on the mode by which certain drugs act upon the uterus, and from the consequent indications it affords as to the conditions under which they may wisely be administered, but also as a contribution to the physiology of non-striped voluntary muscle. Employing the *überlebende* organ—the organ removed with all precautions immediately after the death of the animal (a sheep)—and continuing the circulation through it artificially, Dr. Helme has been able to study its slow rhythmic contractions apart from the influence of the central nervous system and of the changes in the blood supply. From a physiological point of view, his most important observation is perhaps that which brings out the striking difference existing between striped and non-striped muscle as regards the relationship between contraction and blood supply. Whereas a striped muscle during contraction becomes hyperæmic, the uterus, the largest mass of unstriped muscle in the body, becomes during contraction relatively anæmic.

It is impossible to pass Dr. Gulland's articles upon the nature and varieties of leucocytes and upon the development of adenoid tissue without bestowing on them not a little adverse criticism, and this, while appreciating fully the long months spent in laborious preparation and examination of tissues, and in studying the literature of the subject, of which they bear ample witness. That Dr. Gulland bases his conclusions upon the view that the leucocytes are symbiotic, and shows at the outset that he totally misconceives the nature of symbiosis, is quite sufficient to render fuller criticism of his views unnecessary. Yet, that it may not be said that I misrepresent his views, it may be as well to quote his words upon this subject:—

> "There are still" (in the Metazoan) "many functions to be performed which can only be discharged by cells possessed of Protozoan characteristics. . . . To perform these functions it is necessary that a certain number of cells should continue to be practically Protozoa, and these cells are what we call 'leucocytes,' so that we may regard them *morphologically as representing those members of the primitive Metazoan colony which escaped differentiation, and have remained unaltered Protozoa through the whole series of Metazoa*" (the italics are mine).

Such inconsequent theorizing goes far to neutralize the minute and careful observations which Dr. Gulland has made into the histology of his subject.

That the formation of bile solids is more closely associated with the general metabolism than with the changes of digestion is the conclusion drawn by Dr. Noël Paton and Mr. Balfour, though somewhat unexpectedly they find that in fever, where the general metabolism is greatly increased and the digestive processes reduced, the amount of bile solids excreted is diminished. All studies of cases of biliary fistula in man are of value, and such full observations as those here described are rare. Of drugs they find calomel and salicylate of soda active in increasing the flow of bile. Whether they are right in looking upon the bile as an excretion, rather than as at the same time a secretion playing an essential part in digestion, is open to doubt. Even if with bile excluded from the intestine only 30 per cent. of the fats ingested pass out unused, that nevertheless is a proportion large enough to demand consideration, and to support the assumption that as a secretion, as well as an excretion, the bile is of definite importance. The ingenious method devised for the estimation of the bile pigments (p. 197) deserves a more extended trial.

At a time when Koch's endeavours to cure tuberculosis by means of injections of products of growth of the tubercle bacilli have brought the whole subject of bacterio-therapeutics prominently to the fore, the full discussion of this by Drs. Woodhead and Wood is very acceptable, based, as it is, upon their own important discovery that the invasion of the organism by the bacillus of anthrax may be prevented by injections of the sterilized fluid in which the *Bacillus pyocyaneus* has been grown. Space forbids that I should do more than indicate that those interested will here find a full account of our present knowledge of a subject which is occupying the energies of every leading bacteriologist.

Of allied interest is the communication by Dr. Wood and Mr. Ross. It has long been known that the advance of erysipelas can often be successfully combated by painting the skin immediately outside the erysipelatous area with some counter-irritant. The authors have studied the *rationale* of this treatment, and conclude that the irritant brings about the formation of a zone of inflammation, with dilatation of the vessels and diapedesis of the white corpuscles, which now, by destroying the micrococci, act as a barrier to the further progress of the disease. With the malignant pustule produced by the inoculation of the anthrax bacilli, similar counter-irritation was effectual in only three out of thirty cases—that is to say, with the more active virus the stimulus applied was not sufficient to produce an effectual barrier. J. GEORGE ADAMI.

THE CHEMICAL AND BACTERIOLOGICAL EXAMINATION OF POTABLE WATERS.

Examen Químico y Bacteriológico de las Aquas Potables. Por A. E. Salazar y C. Newman, con uno capitulo del Dr. Rafael Blanchard sobre "Los Animales Parásitos introducidos por el Aqua en el Organismo." (London: Burns and Oates, 1890.)

A PECULIAR interest attaches to this work at the present moment in consequence of the sad political events now going on in the country from which it has emanated; for, whilst almost each successive day brings news of the sacrifice of human life in one of the fiercest and most sanguinary civil contests of recent years, the object of this book is to show how the latest results of scientific research may be applied to combating on the same soil some of the ills which flesh is heir to. The publication of this treatise for Chilian students affords the strongest evidence of the rapidity with which scientific knowledge traverses the globe at the present day, and it must be a source of great satisfaction to all interested in the dissemination of the principles of hygiene that there should be a demand for a work of such an advanced character in a country so remote from what we are wont to regard as the centres of civilization.

The scope of this work is more comprehensive than that of perhaps any similar one in our own language; English treatises on water analysis being in general only short manuals giving instructions for the execution of analytical methods devised by their authors, who usually dismiss the rival methods of others with a few words, often not of a very complimentary kind. The pages under review, however, not only give an interesting account of the various methods employed by water-analysts, but subject their several claims to a fair and impartial criticism, whilst detailed information is supplied for carrying out those methods which the authors regard as, on the whole, the most serviceable. Again, a most exhaustive account is given of the bacteriological examination of water, including precise instructions for the cultivation of micro-organisms, the preparation of nutritive media, the sterilization of apparatus, the use of the microscope, and the performance of inoculation experiments on animals. But even this ample programme was inadequate for the ambition of the authors, who have associated with themselves a third colleague, who contributes a bulky appendix on "the animal parasites gaining access to the organism through water." The work is not only profusely illustrated with cuts, but contains also a number of original photographs representing both the microscopic and macroscopic appearance of some bacteria. Indeed, the bacteriological part is the real centre of gravity of the work. A decade will soon have elapsed since the bacteriological examination of waters began to attract much attention in consequence of the ingenious method o gelatin-plate cultivation devised by Koch. It was not, however, until some years later that the method yielded results of any practical importance, inasmuch as it was at first almost exclusively applied by bacteriologists whose previous information on questions of water-supply was of a somewhat limited order, whilst the value of the method for the solution of many hitherto unsolved problems connected with the hygiene of water is even now but imperfectly appreciated by chemists. When the method was first applied to the London water-supply, in the year 1885, it at once brought to light that in the process of sand-filtration, as practised on the large scale, a most astonishing proportion of the micro-organisms present in the unfiltered water were removed, whilst in the best of our deep-well waters the number of microbes found was so small that it seemed probable that the removal of these low forms of life in this process of natural filtration was really complete, and that the few actually found had very likely been imported into the wells from the surface. On the other hand, it was shown that the sand-filters did not wholly remove the organisms present in the unfiltered water, as, in the course of regular examinations carried on over a period of more than three years, a most unmistakable relationship between the number of microbes present in the unfiltered and filtered waters respectively was discernible. The scope of the bacteriological method of examination became very much narrowed when it was discovered that there are many micro-organisms which have the power of multiplying to an enormous extent in the purest waters, including distilled water itself, so that the number of microbes present in a given sample of water affords no indication *per se* of the purity or otherwise of the water. This disturbing element in the bacterioscopic examination of water is not sufficiently emphasized by the authors. But this extraordinary phenomenon of multiplication, although it invalidates the bacteriological process for the general purposes of water examination, does not at all interfere with its successful application to the investigation of the efficiency of filtration, either natural or artificial, provided that the filtered water is subjected to examination without delay after it has undergone the process of filtration.

It should be pointed out that there exists a very widespread misapprehension as to the ideal object of the bacteriological examination of waters, and the authors of this work fall into the same error to some extent also. It is very generally supposed that the main object of a bacteriological examination is to discover whether or not there are disease-producing organisms, *e.g.* those of typhoid, in the water. But this is a point really of very limited importance, and what should be kept in view in an examination of water is the endeavour to discover, not whether the water contains zymotic poison at the time of analysis, but firstly, whether it is exposed to influences which may at any time lead to the introduction of such zymotic poisons, *e.g.* through contamination with sewage;

and secondly, whether, if such organized poisons should gain access, there is any sufficient guarantee or not that they will be destroyed or removed before the water reaches the consumer. It is because the chemical analysis affords us at present a better clue than the bacteriological examination as to whether a water has received sewage or not that it is of more general applicability than the latter; but we must appeal to a bacteriological inquiry in order to ascertain whether, in the event of sewage gaining access to the water, there is a guarantee in the subsequent history of the water that the zymotic poisons, which may at any time accompany the sewage, would undergo removal. In short, the object of nearly all water examinations is obviously to ascertain whether the water may at any time be dangerous to health, and not, even if this could be with certainty determined, whether it contains a zymotic poison at the particular moment of examination. On the other hand, the fact that the microbe, which is now pretty generally accepted as the inducing cause of typhoid fever, has been on more than one occasion actually discovered in drinking-water which was under suspicion of producing an epidemic of that disease, affords most important evidence as to the manner of its distribution.

There is much need of a similar work to this in English, as each year an increasing number of younger medical men are coming forward for the degrees in Public Health which are now granted by several of our Universities, and to these a practical and critical treatise such as this would prove of great value. It is of great importance that such Public Health students should be impressed with a sense of the responsibility which attaches to the examination of waters for domestic purposes, and that most serious mischief may and often does result from such investigations being intrusted to incompetent persons. It is gratifying to see that the authors do not undertake to prescribe any of those artificial standards of purity for drinking-water which so frequently figure in books of this kind, and which are attended with the greatest danger, leading as they do the ignorant to believe that they can pronounce upon the fitness or otherwise of water for drinking purposes from the numbers which they have obtained in a few simple quantitative determinations. For it must never be forgotten that the sanitary examination of water is surrounded with such difficulties that it is only by bringing to bear on each particular case all the evidence that it is possible to obtain, and then interpreting this evidence by the light of an extended experience, that a sound judgment can be arrived at.

OUR BOOK SHELF.

Botany: a Concise Manual for Students of Medicine and Science. By Alex. Johnstone, F.G.S. (Edinburgh and London: Young J. Pentland, 1891.)

DURING recent years many books on botany have been published, specially for the use of students preparing for examinations. In these a few types and phases of plant life have been described somewhat in detail. In the present case a much wider range has been taken, the result being an illustrated botanical note-book, condensed but not meagre. In the preface the author takes it for granted that every student nowadays attends lectures or demonstrations, and "therefore does not so much require a manual with diffuse explanations, but rather a kind of illustrated digest and general note-book, which will enable him to quickly arrange and make most effective use of the various facts and theories treated of by his teacher." A book on these lines Mr. Johnstone has been successful in producing. It consists of 260 pages and 226 illustrations. Some of the latter are the ones which seem by custom to be considered necessary for reproduction in every fresh botanical manual, while others appear to be new. The outline ones, such as those on p. 30, illustrating the branching of cells, give a much clearer idea than could be done by pages of letterpress. A short introductory chapter points out the position botany holds in science. The strictly botanical part of the work is treated of in four sections, viz. (1) morphology; (2) external morphology or organography; (3) physiology; and (4) taxonomy.

Under morphology, the structure, life-history, contents, and modifications of the cell as an individual are first treated of, after which the combinations of cells to form tissues are described, a special chapter being reserved for the consideration of systems of permanent tissues. The section on external morphology will be found very useful to beginners in systematic botany. It could be wished that the chapter on physiology, although containing much useful information in its 15 pages, had been more extended. The greater part of the remainder of the book is devoted to taxonomy, in which the leading characters of each class (arranged in ascending order) are given, followed by the names of some of the genera, which may be regarded as typical of their respective classes, and interspersed with illustrations. The orders of Angiosperms most frequently met with are represented by short diagnoses and floral diagrams. A useful glossary and index complete the book.

The arrangement throughout the book is good. The various headings, &c., printed in type differing according to their importance, have been very carefully set out, and give a good *résumé* of botany in a tabular form. As an illustrated note-book for a teacher, as well as a student, this work will be found of great use.

C. H. W.

Hand-book of the Ferns of Kaffraria. By T. R. Sim, Curator of the Botanic Garden, King Williamstown, South Africa. 66 pages, 63 plates. (Aberdeen: Taylor and Henderson, 1891.)

THIS little book contains popular descriptions and outline plates of the ferns of Kaffraria, with a chapter of definitions of the botanical terms used in describing ferns, and another giving directions how to cultivate them. The Cape, considering the general interest and remarkable individuality of its phanerogamic flora is very poor in ferns. Kaffraria yields only 68 species, about the same number as Great Britain. Amongst them are two tree ferns, a Cyathea and a Hemitelia, and several herbaceous species of a distinctly subtropical type, such as *Vittaria lineata* and *Marattia fraxinea.* Associated with these are several species with which we are familiar at home, such as *Aspidium aculeatum*, *Cystopteris fragilis*, and *Adiantum Capillus-Veneris.* No doubt by further exploration the list will be considerably increased. The author does not seem to have known anything about the Rev. R. Baur, a Moravian missionary who made large collections of ferns and other plants in Transkeian Kaffraria. The two new species which Mr. Sim claims to have added to the Cape flora cannot be admitted as novelties. *Blechnum remotum* is a variety of the American *B. hastatum*, which I do not think can stand as distinct specifically from the common Cape *B. australe.* The plant figured as *Lomaria lanceolata* on Plate 25 is no doubt *Lomaria inflexa* of Kunze, which was gathered long ago in the colony, by Gueinzius, and is beautifully figured by Kunze from specimens which he forwarded. By the aid of this book there can be no difficulty, even to an amateur, in recognizing any of the Kaffrarian species ; and perhaps at some future time Mr. Sim, who was trained at Kew, will extend his area so as to cover the whole colony, for which the total number of ferns known is between 130 and 140.

J. G. Baker.

Rider Papers on Euclid. Books I.–II. By Rupert Deakin, M.A. (London : Macmillan and Co., 1891.)

This little book consists of a series of graduated riders so arranged that the beginner may be able to thoroughly understand and grasp the principal propositions of the first two books of Euclid. One of the chief errors that the author endeavours to avoid is the great stress teachers lay on some of the propositions, which are treated as most important, while others are more or less overlooked.

The method he adopts is to treat each proposition first as a rider, and by giving the enunciation and drawing the figure, see if any of the class can show how it is proved. By this means the subject can be made interesting, as beginners can then look upon each rather as a puzzle than as a stiff piece of work.

The two books are divided into nine parts, each part consisting of six papers, and the riders in each paper, with the exception, of course, of the first, deal with all the preceding propositions. The student is advised in the first six papers only to draw the figures, in order to accustom himself to one of the chief difficulties which, as the author says, " experience shows me that all students feel more or less in solving riders."

At the end are printed the enunciations of the propositions of the two books, followed by several papers set at various examinations. Altogether, teachers will find this an admirable help for classes in which the subject is being treated for the first time.

Die Krystallanalyse oder die chemische Analyse durch Beobachtung der Krystallbildung mit Hülfe des Mikroskops mit theilweiser Benutzung seines Buches über Molekularphysik. Bearbeitet von Dr. O. Lehmann. (Leipzig : Engelmann, 1891.)

We have so recently noticed at length the splendid work of Dr. O. Lehmann on "Molecular Physics" (see Nature, vol. xlii. p. 1) that it is only necessary in this place to call attention to this pamphlet of 82 pages, illustrated by 73 woodcuts, in which the author gives the necessary directions for the work of micro-chemical analysis. The instruments used and methods employed are concisely stated, and all the essential details of the operations are supplied to the chemist in this little handbook. Dr. Lehmann claims, not unjustly, that the methods of micro-chemical analysis must play the same part in the laboratory of the organic chemist as spectral analysis does in the laboratory of the inorganic chemist.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

The University of London.

My friend, Mr. Thiselton Dyer, invites me, by his references to what I have written on this subject, to a discussion in your columns. I am very unwilling to accept the invitation, because I have already and often stated my views, and because I see by the length of Mr. Dyer's letter that I may be led into an interminable labyrinth of side-issues. The official report in which are published the minutes of the evidence given before the Royal Commission which sat on this subject in the year 1888, contains a more lengthy discussion of the subject by myself and others than it is possible to carry through in the columns of Nature ; and I could wish that for once those interested in a subject would rescue from proverbial oblivion the pages of careful statement entombed in a Blue-book. Since, however, my friend trails his coat, it would be doing violence to my old-established regard for him to refuse to tread on it—just a little.

The question raised by Mr. Dyer seems to be, why should not the examining board in Burlington Gardens undergo certain reforms and continue to be the so-called University of London? It has done good service to education, he says, and with the removal of more than half its members and their replacement by gentlemen who either really know or really care about University education it might do more. If it were, he suggests, to rise superior to all its most solemn obligations and falsify the pledges of its founders by undertaking to teach as well as to examine, it would really be as much of a "teaching University" as is either Oxford or Cambridge, and its non-collegiate supporters from all parts of Britain might enjoy the spectacle of the mother-college (University College) from which this examining board took birth, abandoning in favour of Burlington Gardens those traditions of scientific research which have made the College in some measure a realization of Fichte's ideal.

[Mr. Dyer seems to have forgotten the facts when he contends that such teaching as Fichte sketched in his plan for the University of Berlin, cannot be carried on in the same institution or by the same men who administer the teaching required by a University student at the commencement of his career. Fichte's plan was carried out in the University of Berlin, and has been followed by every other University in Germany. The very questions which we are now debating were debated in the early years of this century in Germany, and the Jesuits' plan of education by examination was rejected. University College was founded (except so far as it was a private enterprise) on the lines of a German University, and only required the *prestige* and independence conferred by the power of granting University degrees to enable it to fulfil in London Fichte's ideal. Its professors have never been (as Mr. Dyer well knows) mere instructors for examination purposes. The researches of Graham, Williamson, Sharpey, and of Michael Foster, Sanderson, Schäfer, Kennedy, and many others have been carried on in its laboratories. The proposal to detach such work from the London Colleges, and to associate it with the examining board in Burlington Gardens, on the ground that it is inconsistent with the teaching of University undergraduates, appears to me to involve an erroneous conception of what University education and University organization should be. This by way of parenthesis.]

The point which I wish to insist on is that, excepting the proposal to undertake higher professorial teaching, I have no objection whatever to the reforms of the examining body in Burlington Gardens advocated by Mr. Dyer.

What I desire (and I merely use the first person singular for the purpose of discussion, and not because I stand alone in my wishes, or undervalue the support of others) is that, without any interference with the Burlington Gardens board, the privilege of granting degrees should be conferred by the Crown upon a combined Senate consisting of the Professors of University and King's Colleges (the authority of the councils of the two Colleges being duly guarded).

The fact that Burlington Gardens are in London and that University and King's College are also in London, as well as the talk about a teaching University "in and for" London, have very little bearing upon the question as to whether it is or is not desirable to grant University privileges to the two Colleges. There is population enough and accommodation enough for a dozen Universities within the metropolitan area. As far as I am able to judge as to the principles which should guide the Crown in bestowing the privilege of incorporation as a University, the only questions to be asked are : "Does the body which asks for this privilege consist of learned men whose work will be facilitated by the granting to them of this ancient and honourable position? Do they give guarantees of material support, and of a public demand for their teaching, which will enable them to discharge the functions of a University with dignity and efficiency, now and hereafter? Will the concession to them of this privilege tend directly or indirectly or both to the public welfare?" I cannot imagine that anyone will undertake to give a negative response to these questions in reference to the combined Colleges, University and King's. Certain it is that during the acute discussion which has been carried on for the last four or five years, no one has ventured to do so. What has happened is simply this, that persons connected with Burlington Gardens have opposed the bestowal of University powers on the two Colleges, either for the reason that they consider the withdrawal of the Colleges from the sphere of the operations of the Burlington Gardens examining board a reflection upon that body, or because they are unwilling that a privilege should be conceded to Colleges, however well fitted to receive it, which their own local or provincial college is not yet important enough to claim. A further incident of the movement has been that the just demands of London medical students and their teachers for a University degree in medicine, as readily attainable by London students as are the medical degrees of Edinburgh, Glasgow, Dublin, Aberdeen, St. Andrews, Durham, and Cambridge, by the students of those places, have been formulated and generally approved.

Neither of these accompaniments of the request for University powers made by University and King's Colleges seems to me to touch the question as to whether it is right on grounds of public policy to accede to that request. Sir William Thomson, Sir George Stokes, and Mr. Weldon after an exhaustive inquiry were in favour of granting the privilege asked for. Three lawyers, namely Lord Selborne, Sir James Hannen, and Sir James Ball, were not persuaded. The commission composed of these six gentlemen agreed to ask the Burlington Gardens authorities to try to devise such alterations in their "University" as would satisfy the aspirations of University and King's Colleges. Burlington Gardens has absolutely and hopelessly failed in this attempt—as anyone conversant with the conditions of the problem could foresee must be the case. They have proposed a scheme which has not been accepted by the Colleges, and has also been rejected by their own provincial graduates. Why should more time be wasted about the attempt to put three pints into a quart bottle? Let the Burlington Gardens University continue to exercise its function of examining for schools and colleges which are not strong enough to examine for themselves, and let them continue so to do only until the colleges are fit to receive independent University powers; let the Senate reform itself if it can, and if the absurd dead-weight of graduates tied round its neck and called Convocation will permit it to do so. But do let us have in the meanwhile a genuine professorial University set on foot in London, not because it is London, but because University and King's Colleges are there, and respectfully petition Her Majesty to do for them what the monarch has done (not unwisely, it must be allowed) in past days for the Senatus Academicus of Edinburgh, of Aberdeen, of Leyden, of Berlin, Bonn, Leipzig, and other cities.

What the two Colleges ask for is a privilege—a special favour. To include other institutions as co-recipients of the privilege would destroy its character and its value. As Mr. Dyer points out, we do not want a federal University, such as are Cambridge and Oxford and the Victoria. We have seen enough of the friction and never-ending committees and schedules of such clumsily organized Universities. By limiting the charter to University and King's Colleges, a professorial University can be established in which the professors shall be—as in the Scotch and the German Universities—at once the teachers, the examiners, and the governing body. I cannot perceive what good can be attained by joining a series of rival teaching bodies together, calling them a University, and setting them to waste the lives of their lecturers in committees and boards and the drawing up of schedules. The only persons who gain by such wasteful arrangements are the busybodies and bureaucrats, who either acquire importance by their intermediation in the disputes of rival teachers, or gain a livelihood by pompously conducting the affairs of the committees and boards in which what is good and strong in each member is counteracted, whilst only what is feeble, worthless, and emasculate survives.

The professorial University formed by a union of King's and University would be of modest dimensions, and rightly so. It would in virtue of its charter be able to grow. This I regard as the most important feature in the proposal. Instead of hastily bringing together a variety of teaching bodies, we should leave it to the new University to assimilate them, make terms with them, in the course of time.

Though they are modest bodies compared with the Imperial centralizing institution, from the thraldom of which they seek to escape, yet King's and University Colleges can show figures stating the property and the number of students which they would bring to the new University, which are far larger than the corresponding figures for many other Universities both in the United Kingdom and abroad. Their buildings and land are worth half a million sterling. Their annual receipts exceed £30,000; their annual attendance of students is as great as that of the University of Oxford. This is an ample basis; with this start the new University would without any doubt be able to ensure a steady growth, increase of its property and of its teaching capacities, by a healthy and gradual development.

Mr. Dyer skilfully seeks to enlist support for the supremacy of Burlington Gardens by asking the following questions (to which he does not give the answers for obvious reasons): "Why should two out of many institutions be picked out for University honours? Why should Bedford College be left out? How can the Royal College of Science be ignored? Why ignore the City and Guilds Institute?"

These questions are excusable only when we admit that Mr. Dyer may for the nonce treat his defence of Burlington Gardens as a lawyer may treat a shady case entrusted to his advocacy in the courts.

The reason why the Crown should pick out the two Colleges for the University privilege is, firstly, that they and they alone have asked for it; secondly, that they and they alone possess the property, professoriate, status, and historical purpose which could warrant the privilege; and, lastly, that University powers are essentially a privilege fitted and intended to strengthen and build up the institution to which they are granted above others. Bedford College is cited by Mr. Dyer solely, I am afraid, with the purpose of rousing the jealousy of its members. They are, I hope and believe, too sensible to be led to imagine that their excellent institution is at all comparable in magnitude or importance to University and King's. As to the Royal College of Science, the answer is different. It is a Government institution under a special department founded and carried on with a special purpose. It grants its own certificates and fulfils its objects. I see no objection to its receiving the privilege of granting those certificates in the form of University degrees; but it could not be associated with University and King's Colleges to form one Senatus Academicus. To introduce it or the City and Guilds Institute into the new University would necessitate the formation of what I am persuaded would be a pernicious and futile organization—namely, a federal University. And, moreover, it appears that both the Royal College or Normal School of Science and the Guilds Institute were founded with public money and are carried on for other purposes than that of training University students, and that their managers do not seek the privilege of granting University degrees nor consider that their public utility would be increased by any such federation with the new University as Mr. Dyer suggests. There is plenty of room in London for non-University Colleges as well as for more than one University. The objectionable notion which Mr. Dyer and some others entertain is that these institutions can be made more useful by arbitrarily bringing them under the control of some central government—such as is now exercised by Burlington Gardens.

The fact appears to me to be that centralization in University matters is wasteful of time and energy, paralyzing and delusive. Two Colleges like University and King's can unite and settle their affairs together, and if granted such powers as other Universities possess they may in time take into their organization, partially or completely, other institutions, or arrange methods of co-operation with other institutions. Indeed they would, if incorporated as a University, be sure to do this, and to do it far more efficiently than could be the case were they abruptly associated with a variety of rival corporations, each with equal rights and equal voice, and left to compromise and to vote through endless committees, either as constituents of a reformed Burlington Gardens University or of a new piece of federal futility.

Mr. Dyer has wisely avoided the question of the demand for medical degrees. I confess that this is a very difficult problem on account of the attitude of the medical profession. If the medical profession is to be allowed to grant medical degrees, the present significance and a good deal of the value of the University privilege will be destroyed. It is, I believe, quite useless to attempt to *satisfy* the demands of the medical profession in this matter. The thing to be aimed at is to remedy an injustice; it is necessary to provide a degree as accessible as that of other Universities through whatever University or Universities may exist, hereafter, in London.

In my evidence to the Commissioners I made some suggestions on this matter. I am inclined to think that the following steps are necessary for a satisfactory solution of the problem: (*a*) the abolition of the medical faculties of University and

King's Colleges—excepting the Professorships of Anatomy, Physiology, Pathology, and Forensic Medicine—and the creation of independent clinical schools attached to the North London and Lincoln's Inn Hospitals; (*b*) the nomination of a medical professoriate for the new University by representatives of all the London medical schools, vacancies to be hereafter filled up on the recommendation of the Senate of the University; (*c*) the recognition, under conditions, by the new University, of the clinical teaching in each of the London hospitals, and the admission of students to its medical degrees on condition of having passed the prescribed examinations of the University and of having pursued not necessarily more than one-half of the entire curriculum under the professors of the University. The University might also be required to recognize (in exchange for a like concession) the examinations in certain subjects of the Conjoint Board as excusing candidates from like examination by the University.

This is undeniably a complex part of the subject. It would be simplest, and probably satisfactory in the end, to grant the power of giving medical degrees to the limited body (King's and University) and to leave it to make such arrangements as it might find expedient with the medical schools of London. The professional feeling of the medical faculties of University and King's Colleges would insure their making an equitable use of the privilege, such as their medical brethren would heartily approve.

E. RAY LANKESTER.

P.S.—There is one argument put forward by Mr. Dyer which I have omitted to notice in the foregoing, but should like to tread on. He quotes my opinion that the University may usefully examine scholars passing from the schools to the University as a test both of the work of the schoolboy and of the efficiency of the schoolmaster, and proceeds to maintain that in the same way an examining board may usefully check not only the work of University undergraduates, but of their teachers. This is advanced as an argument in favour of external or superior examining boards in University examinations as opposed to examinations conducted by University professors with associated external examiners. Mr. Dyer has, however, omitted to cite the reply which I had already given to his specious argument. It is this: the University is the highest term in the educational hierarchy. It may fittingly examine students who are about to pass from the school to continue their studies on a higher level, viz. its own. But who or what are the persons recognized as standing above the University professoriates? I do not know of any such body. It is precisely the arrogation of this position for the Senate of the University of London which renders it objectionable. There is necessarily a limit to the organization of authority in educational matters, and it is as absurd for the members of a central examining board to control the teaching of those who are *ex hypothesi* the most capable teachers in the country as it is for the Home Office to control the details of the work of the Senate of Burlington Gardens. Either University professors are worthy to occupy their positions or they are not—no higher branch of the educational profession exists. To coerce them by means of Senates composed of retired teachers and *dilettanti* educationists is clearly injurious: to set them to work to criticize and worry one another as "impartial examiners" is odious and a waste of their time. The only thing to do is to take such measures as are possible for insuring that no one who is not fit for the position shall hold office as a professor in a chartered University, and to so arrange that it shall be to the interest of the professor, and also to that of his University, for him to discharge his duties efficiently.

If we are to have an indefinite series of authorities one above the other, who, one would like to know, is to control the examining board which sits over the professors? And who again to control these controllers?

The bureaucratic machinery which seems to find favour with Mr. Dyer is, in my opinion, superfluous. The most efficient Universities (in two differing directions), those of Germany and of Scotland, have no authority in educational matters above that of the professoriate, and are not subject, like Oxford, Cambridge, and London, to the interference of graduates in the form of convocation.

MR. THISELTON DYER appears to think that Fichte's ideal of a University is unrealizable, unless, as he supposes, "some wealthy man gives, say, half a million to found such a University in some quiet country town in England, where professor and pupils might labour together, undisturbed by the life and movement of a big city, or the worry of the examination-room, for the advantage of knowledge." I venture to think that this supposition of Mr. Thiselton Dyer's conveys the unwelcome truth that the conception of the true nature of a University has not yet reached some even of that section of the British public who have earned well-merited distinction in science; and it is as one who has had experience of a Scottish and a German University, in the character of student and teacher, and of two English University Colleges as teacher, that I ask permission as shortly as I can to place before your readers what many minds aim at, in the hope that a teaching University in London, call it what you will, would ultimately provide it.

I reiterate the assertion which I lately made in a letter to the *Times*, that a University is primarily a place for the extension of the bounds of knowledge; this is to be achieved by the labours of the professors and teaching staff; by fellows, specially appointed for that purpose, if the system of fellowships is thought desirable, although, in my opinion and experience, much may be said against it; and by the *whole body of the students*. Of course it is not to be supposed that every student is capable of discovering new facts or of applying principles in an original manner; but almost every man is endowed with some share of inventive faculty, which must ultimately be developed, if he is to make his way in the world otherwise than as a day-labourer, or as a piece-worker in a factory, or as a copying-clerk; and the object of a University should be to cultivate this faculty to the utmost. An efficient medical man spends his life in clinical experimentation; a successful barrister exercises his ingenuity in applying old decisions to new cases; a competent engineer not merely studies how to improve his machinery, but also studies his fellow-creatures, and the chances of trade, so as to bring his manufactures into new fields. If the inventive faculty is not developed at the University, it will be developed later, in every man who fulfils his duty to his fellow-creatures and to himself.

Now I dare to contend that the degree-stamp of the English Universities, especially of the University of London, except in certain cases in its highest degrees, such as the D.Mus., D.Litt., M.D., and D.Sc. degrees (and these only as a result of recent modifications), is of no value whatever in the eyes of that portion of the public whose opinion carries with it a commercial reward. Speaking for myself, I have had assistants, graduates of Edinburgh, of London, and of German Universities, and I unhesitatingly state that the only degrees to which I should attach the least importance are those of Germany, and that because there is in them some evidence that the graduate has had at least an initiation into the methods of research. As this assertion may be applied personally, I should wish it to be clearly understood that I have no reason whatever to be in any way dissatisfied with graduates from Edinburgh or from London, but merely to state that the fact of their being graduates in no way influenced me in their appointment. And many manufacturers, in want of assistants, actually regard an English degree in the light of a disqualification; so that most of the posts of "works-chemists" are held by non-graduates. They prefer, in fact, to train their own men—that is, to give them such an education in research as bears on the particular problems which they themselves have to solve; or to take them from the laboratories of general analysts, where new problems present themselves from time to time.

It is impossible, under existing circumstances, to give undergraduates such training. They have examination on the brain. They judge from the standpoint of "Will this 'pay' at an examination?" not from the standpoint of "Is this worth knowing?" And they cannot be blamed. It is not the fault of the examiners; it is not the fault of the students; the professors, I believe, do not, except in a general way, follow the syllabuses; it is simply that the better students conscientiously aim at what is set before them—a degree that has no market value, except in the eyes of school teachers. Personally I cannot complain that I do not get research done by students; in actual fact a considerable number do stay after graduation, and some do not graduate at all; I merely hold the opinion that the method is on wholly wrong lines; that a degree, if given, should be the official testimony to a certain time spent with diligence and profit in gaining knowledge of how to attack problems—of how to acquire knowledge useful for the purpose in view.

It will be said that honours-degrees will find no place in such a system. Why should they? Does the desire to beat competitors stimulate a desire for knowledge? Does it stimulate originality? I for one would willingly see them non-existent.

Up to a certain point, the acquisition of knowledge of facts should be, as at present, tested by examination; but I am convinced that the system is at present pushed to an extreme, and that much better results would be gained by giving a degree for training, and that can be done only by the trainer—the teacher. He will, as a rule, be glad to share his responsibility with, and to benefit by the advice of, an outsider; but with him should ultimately rest the decision as to the merit or demerit of a candidate, as he is the only person able to judge. Under such a system, there would be little plucking; for the student would be advised not to present himself, unless he had sufficiently qualified.

It may also be said that undue advantage would be taken by the teacher in recommending unfit students for graduation. Teachers in such positions are, I believe, generally honourable men; they are chosen after the most careful inquiry into their past career. It is not held fitting in commercial circles to appoint a clerk or an accountant on good recommendations, and after sufficient apprenticeship, and then to surround him with safeguards, in case he turn out incapable or dishonest.

The objection may possibly be raised, that under such a system the standard of degrees would be very uneven; but what of that? As at present, anyone applying for a post of any kind would furnish a reference to his teachers; and a private letter from one well acquainted with the candidate turns the scale, for or against, in spite of every degree in the United Kingdom.

In plain English, degrees, as at present given, are not valued by that portion of the public qualified to judge; and we must face this fact, and endeavour to render a degree a real mark of merit.

I believe, with Mr. Dickins, that the examinations of the University of London have done much in disseminating knowledge, and they have therefore proved of great service, but except in the case of the higher degrees before mentioned, and of the degrees in the Faculty of Medicine where evidence of training is a *sine quâ non*, I greatly doubt whether they have contributed towards the creation of knowledge, or training in originality. And from the very nature of the constitution of the University of London, it is impossible that it should be otherwise. This very morning, I happened to ask a student attending my lectures on organic chemistry why he, a B.Sc. in chemistry, was attending my lectures. His reply was characteristic. "I scamped up enough of the subject privately, sir, to squeeze through; but now I wish to know it." In any right system, such a proceeding should be impossible.

It is therefore with the hope that the creation of a teaching University for London might tend to remedy such evils, that I, for one, would welcome it. I would urge that the distinguished names mentioned by Mr. Thiselton Dyer are surely guarantees that the London Colleges recently possessed men capable of imparting the highest standard of knowledge, and of stimulating true originality; yet I believe that it is by no means "cutting cheese with a razor" to employ just such men in watching over the development even of junior students; and it is not without advantage to the most able men of science and of letters to be obliged periodically to devote consideration to "elements" and to pass in review first principles. It counteracts the tendency towards specialization, which, however valuable, always limits the mental horizon. I will undertake to say that the quality of the most advanced teaching in biology and physiology in University College when the chairs were occupied by Burdon Sanderson, by Michael Foster, and by Lankester knew no limit; and I greatly doubt the wisdom of appointing teachers whose attention is to be devoted exclusively to research. As my predecessor, Prof. Williamson, often remarked, it is more difficult to teach junior than to teach senior students; and while the superintendence of exercise and laboratory work may well be shared by assistants, in order that the professor may have time to devote to research, and to superintendence of advanced students, it would be a serious calamity were the influence of such minds to be withdrawn wholly from the juniors.

It is precisely by such a federation of Colleges such as University and King's, and of other sufficiently qualified institutions which have the will and the power to join, that specialization may ultimately be effected. The future occupants of the chairs may be chosen so as to represent every side of a subject; and anyone wishing to pursue research in any special branch would have no difficulty in selecting that particular college where his specialty was also the specialty of the teacher.

WILLIAM RAMSAY.

No well-wisher of the University can feel otherwise than grateful to you for affording a portion of your valuable space for the letters of Mr. Thiselton Dyer and Mr. Dickins on this subject. No two men could be found to speak with greater authority from first-hand knowledge of the facts. The arguments on the subject have been too much of an *ex parte* character hitherto, not seldom based on insufficient information or erroneous impressions. Nothing, for example, could be further from the truth than the statement in the *Times* of May 13, by the writer of what was upon the whole a fair and comprehensive leading article, that "there is no reason why the highest honours of the University of London should not be obtained by a person who never set foot in London or even in England." Many, who like myself voted for the projected scheme of the Senate, must have felt, as I did, as a result of a wide and varied educational experience, that it was potential with great good in the future, and could be accepted as the working basis of the future development of the University, although we felt that the one serious blot in it was the abandonment of uniformity in the examinations for the pass degrees. I verily believe that this was the one thing fatal to its success in Convocation; that it was so far in excess of the recommendations of the Royal Commission as to be unwarrantable; and that it put a lever into the hands of the opposition, of which—as the event proved—a practised disputant like Mr. Bompas did not fail to make most effective and disastrous use.

Wellington College, Berks, May 25. A. IRVING.

Quaternions and the "Ausdehnungslehre."

THE year 1844 is memorable in the annals of mathematics on account of the first appearance on the printed page of Hamilton's "Quaternions" and Grassmann's "Ausdehnungslehre." The former appeared in the July, October, and supplementary numbers of the *Philosophical Magazine*, after a previous communication to the Royal Irish Academy, November 13, 1843. This communication was indeed announced to the Council of the Academy four weeks earlier, on the very day of Hamilton's discovery of quaternions, as we learn from one of his letters. The author of the "Ausdehnungslehre," although not unconscious of the value of his ideas, seems to have been in no haste to place himself on record, and published nothing until he was able to give the world the most characteristic and fundamental part of his system with considerable development in a treatise of more than 300 pages, which appeared in August 1844.

The doctrine of quaternions has won a conspicuous place among the various branches of mathematics, but the nature and scope of the "Ausdehnungslehre," and its relation to quaternions, seem to be still the subject of serious misapprehension in quarters where we naturally look for accurate information. Historical justice, and the interests of mathematical science, seem to require that the allusions to the "Ausdehnungslehre" in the article on "Quaternions," in the last edition of the "Encyclopædia Britannica," and in the third edition of Prof. Tait's "Treatise on Quaternions," should not be allowed to pass without protest.

It is principally as systems of geometrical algebra that quaternions and the "Ausdehnungslehre" come into comparison. To appreciate the relations of the two systems, I do not see how we can proceed better than if we ask first what they have in common, then what either system possesses which is peculiar to itself. The relative extent and importance of the three fields, that which is common to the two systems, and those which are peculiar to each, will determine the relative rank of the geometrical algebras. Questions of priority can only relate to the field common to both, and will be much simplified by having the limits of that field clearly drawn.

Geometrical addition in three dimensions is common to the two systems, and seems to have been discovered independently both by Hamilton and Grassmann, as well as by several other persons about the same time. It is not probable that any especial claim for priority with respect to this principle will be urged for either of the two with which we are now concerned.

The functions of two vectors which are represented in quaternions by $S\alpha\beta$ and $V\alpha\beta$ are common to both systems as published in 1844, but the quaternion is peculiar to Hamilton's. The linear vector function is common to both systems as ultimately developed, although mentioned only by Grassmann as early as 1844.

To those already acquainted with quaternions, the first question will naturally be: To what extent are the geometrical methods which are usually called quaternionic peculiar to Hamilton, and to what extent are they common to Grassmann? This is a question which anyone can easily decide for himself. It is only necessary to run one's eye over the equations used by quaternionic writers in the discussion of geometrical or physical subjects, and see how far they necessarily involve the idea of the quaternion, and how far they would be intelligible to one understanding the functions $S\alpha\beta$ and $V\alpha\beta$, but having no conception of the quaternion $\alpha\beta$, or at least could be made so by trifling changes of notation, as by writing S or V in places where they would not affect the value of the expressions. For such a test the examples and illustrations in treatises on quaternions would be manifestly inappropriate, so far as they are chosen to illustrate quaternionic principles, since the object may influence the form of presentation. But we may use any discussion of geometrical or physical subjects, where the writer is free to choose the form most suitable to the subject. I myself have used the chapters and sections in Prof. Tait's "Quaternions" on the following subjects: Geometry of the straight line and plane, the sphere and cyclic cone, surfaces of the second degree, geometry of curves and surfaces, kinematics, statics and kinetics of a rigid system, special kinetic problems, geometrical and physical optics, electrodynamics, general expressions for the action between linear elements, application of ∇ to certain physical analogies, pp. 160–371, except the examples (not worked out) at the close of the chapters.

Such an examination will show that for the most part the methods of representing spatial relations used by quaternionic writers are common to the systems of Hamilton and Grassmann. To an extent comparatively limited, cases will be found in which the quaternionic idea forms an essential element in the signification of the equations.

The question will then arise with respect to the comparatively limited field which is the peculiar property of Hamilton, How important are the advantages to be gained by the use of the quaternion? This question, unlike the preceding, is one into which a personal equation will necessarily enter. Everyone will naturally prefer the methods with which he is most familiar; but I think that it may be safely affirmed that in the majority of cases in this field the advantage derived from the use of the quaternion is either doubtful or very trifling. There remains a residuum of cases in which a substantial advantage is gained by the use of the quaternionic method. Such cases, however, so far as my own observation and experience extend, are very exceptional. If a more extended and careful inquiry should show that they are ten times as numerous as I have found them, they would still be exceptional.

We have now to inquire what we find in the "Ausdehnungslehre" in the way of a geometrical algebra, that is wanting in quaternions. In addition to an algebra of vectors, the "Ausdehnungslehre" affords a system of geometrical algebra in which the point is the fundamental element, and which for convenience I shall call Grassmann's algebra of points. In this algebra we have first the addition of points, or quantities located at points, which may be explained as follows. The equation

$$aA + bB + cC + \&c. = eE + fF + \&c.,$$

in which the capitals denote points, and the small letters scalars (or ordinary algebraic quantities), signifies that

$$a + b + c + \&c. = e + f + \&c.,$$

and also that the centre of gravity of the weights a, b, c, &c., at the points A, B, C, &c., is the same as that of the weights e, f, &c., at the points E, F, &c. (It will be understood that negative weights are allowed as well as positive.) The equation is thus equivalent to four equations of ordinary algebra. In this Grassmann was anticipated by Möbius ("Barycentrischer Calcul," 1827).

We have next the addition of finite straight lines, or quantities located in straight lines (*Liniengrössen*). The meaning of the equation

$$AB + CD + \&c. = EF + GH + \&c.$$

will perhaps be understood most readily, if we suppose that each member represents a system of forces acting on a rigid body. The equation then signifies that the two systems are equivalent. An equation of this form is therefore equivalent to six ordinary equations. It will be observed that the *Liniengrössen* AB and CD are not simply vectors; they have not merely length and direction, but they are also located each in a given line, although their position within those lines is immaterial. In Clifford's terminology, AB is a *rotor*, AB + CD a *motor*. In the language of Prof. Ball's "Theory of Screws," AB + CD represents either a *twist* or a *wrench*.

We have next the addition of plane surfaces (*Plangrössen*). The equation

$$ABC + DEF + GHI = JKL$$

signifies that the plane JKL passes through the point common to the planes ABC, DEF, and GHI, and that the projection by parallel lines of the triangle JKL on any plane is equal to the sum of the projections of ABC, DEF, and GHI on the same plane, the areas being taken positively or negatively according to the cyclic order of the projected points. This makes the equation equivalent to four ordinary equations.

Finally, we have the addition of volumes, as in the equation

$$ABCD + EFGH = IJKL,$$

where there is nothing peculiar, except that each term represents the six-fold volume of the tetrahedron, and is to be taken positively or negatively according to the relative position of the points.

We have also multiplications as follows:—The line (*Liniengrösse*) AB is regarded as the product of the points A and B. The *Plangrösse* ABC, which represents the double area of the triangle, is regarded as the product of the three points A, B, and C, or as the product of the line AB and the point C, or of BC and A, or indeed of BA and C. The volume ABCD, which represents six times the tetrahedron, is regarded as the product of the points A, B, C, and D, or as the product of the point A and the *Plangrösse* BCD, or as the product of the lines AB and BC, &c., &c.

This does not exhaust the wealth of multiplicative relations which Grassmann has found in the very elements of geometry. The following products are called *regressive*, as distinguished from the *progressive*, which have been described. The product of the *Plangrössen* ABC and DEF is a part of the line in which the planes ABC and DEF intersect, which is equal in numerical value to the product of the double areas of the triangles ABC and DEF multiplied by the sine of the angle made by the planes. The product of the *Liniengrösse* AB and the *Plangrösse* CDE is the point of intersection of the line and the plane with a numerical coefficient representing the product of the length of the line and the double area of the triangle multiplied by the sine of the angle made by the line and the plane. The product of three *Plangrössen* is consequently the point common to the three planes with a certain numerical coefficient. In plane geometry we have a regressive product of two *Liniengrösse*, which gives the point of intersection of the lines with a certain numerical coefficient.

The fundamental operations relating to the point, line, and plane are thus translated into analysis by multiplications. The immense flexibility and power of such an analysis will be appreciated by anyone who considers what generalized multiplication in connection with additive relations has done in other fields, as in quaternions, or in the theory of matrices, or in the algebra of logic. For a single example, if we multiply the equation

$$AB + CD + \&c. = EF + GH + \&c.$$

by PQ (P and Q being any two points), we have

$$ABPQ + CDPQ + \&c. = EFPQ + GHPQ + \&c.,$$

which will be recognized as expressing an important theorem of statics.

The field in which Grassmann's algebra of points, as distinguished from his algebra of vectors, finds its especial application and utility, is nearly coincident with that in which, when we use the methods of ordinary algebra, tetrahedral or anharmonic co-ordinates are more appropriate than rectilinear. In fact, Grassmann's algebra of points may be regarded as the application of the methods of multiple algebra to the notions connected with tetrahedral co-ordinates, just as his or Hamilton's algebra of vectors may be regarded as the application of the methods of multiple algebra to the notions connected with rectilinear co-ordinates. These methods, however, enrich the field to which they are applied with new notions. Thus the notion of the co-ordinates of a line in space, subsequently introduced by Plücker, was first given in the "Ausdehnungslehre" of 1844. It should also be observed that the utility of a multiple algebra, when it takes the place of an ordinary algebra of four co-ordinates, is very much greater than when it takes the place of three co-ordinates, for the same reason that a multiple algebra taking the place of three co-ordinates is very much more useful than one taking the place of two. Grassmann's algebra of points will always command the admiration of geometers and analysts, and furnishes an instrument of marvellous power to the former, and in its general form, as applicable to space of any number of dimensions, to the latter. To the physicist an algebra of points is by no means so indispensable an instrument as an algebra of vectors.

Grassmann's algebra of vectors, which we have described as coincident with a part of Hamilton's system, is not really anything separate from his algebra of points, but constitutes a part of it, the vector arising when one point is subtracted from another. Yet it constitutes a whole, complete in itself, and we may separate it from the larger system to facilitate comparison with the methods of Hamilton.

We have, then, as geometrical algebras published in 1844, an algebra of vectors common to Hamilton and Grassmann, augmented on Hamilton's side by the quaternion, and on Grassmann's by his algebra of points. This statement should be made with the reservation that the *addition* both of vectors and of points had been given by earlier writers.

In both systems as finally developed we have the linear vector function, the theory of which is identical with that of strains and rotations. In Hamilton's system we have also the linear quaternion function, and in Grassmann's the linear function applied to the quantities of his algebra of points. This application given those transformations in which projective properties are preserved, the doctrine of reciprocal figures or principle of duality, &c. (Grassmann's theory of the linear function is, indeed, broader than this, being co-extensive with the theory of matrices; but we are here considering only the geometrical side of the theory.)

In his earliest writings on quaternions, Hamilton does not discuss the linear function. In his "Lectures on Quaternions" (1853), he treats of the inversion of the linear vector function, as also of the linear quaternion function, and shows how to find the latent roots of the vector function, with the corresponding axes for the case of real and unequal roots. He also gives a remarkable equation, *the symbolic cubic*, which the functional symbol must satisfy. This equation is a particular case of that which is given in Prof. Cayley's classical "Memoir on the Theory of Matrices" (1858), and which is called by Prof. Sylvester the Hamilton-Cayley equation. In his "Elements of Quaternions" (1866), Hamilton extends the symbolic equation to the quaternion function.

In Grassmann, although the linear function is mentioned in the first "Ausdehnungslehre," we do not find so full a discussion of the subject until the second "Ausdehnungslehre" (1862), where he discusses the latent roots and axes, or what corresponds to axes in the general theory, the whole discussion relating to matrices of any order. The more difficult cases are included, as that of a strain in which all the roots are real, but there is only one axis or unchanged direction. On the formal side he shows how a linear function may be represented by a quotient or sum of quotients, and by a sum of products, *Lückenausdruck*.

More important, perhaps, than the question when this or that theorem was first published is the question where we first find those notions and notations which give the key to the algebra of linear functions, or the algebra of matrices, as it is now generally called. In vol. xxxi. p. 35, of this journal, Prof. Sylvester speaks of Cayley's "ever-memorable" "Memoir on Matrices" as constituting "a second birth of Algebra, its *avatar* in a new and glorified form," and refers to a passage in his "Lectures on Universal Algebra" from which, I think, we are justified in inferring that this characterization of the memoir is largely due to the fact that it is there shown how matrices may be treated as extensive quantities, capable of addition as well as of multiplication. This idea, however, is older than the memoir of 1858. The *Lückenausdruck*, by which the matrix is expressed as a sum of a kind of products (*lückenhaltig*, or open), is described in a note at the end of the first "Ausdehnungslehre." There we have the matrix given not only as a sum, but as a sum of products, introducing a multiplicative relation entirely different from the ordinary multiplication of matrices, and hardly less fruitful, but not lying nearly so near the surface as the relations to which Prof. Sylvester refers. The key to the theory of matrices is certainly given in the first "Ausdehnungslehre," and if we call the birth of matricular analysis the second birth of algebra, we can give no later date to this event than the memorable year of 1844.

The immediate occasion of this communication is the following passage in the preface to the third edition of Prof. Tait's "Quaternions":—

"Hamilton not only published his theory complete, the year before the first (and extremely imperfect) sketch of the 'Ausdehnungslehre' appeared; but had given ten years before, in his protracted study of Sets, the very processes of external and internal multiplication (corresponding to the Vector and Scalar parts of a product of two vectors) which have been put forward as specially the property of Grassmann."

For additional information we are referred to art. "Quaternions," "Encyc. Brit.," where we read respecting the first "Ausdehnungslehre":—

"In particular two species of multiplication ('inner' and 'outer') of directed lines in one plane were given. The results of these two kinds of multiplication correspond respectively to the numerical and the directed parts of Hamilton's quaternion product. But Grassmann distinctly states in his preface that he had not had leisure to extend his method to angles in space. . . . . But his claims, however great they may be, can in no way conflict with those of Hamilton, whose mode of multiplying *couples* (in which the 'inner' and 'outer' multiplication are essentially involved) was produced in 1833, and whose quaternion system was completed and published before Grassmann had elaborated for press even the rudimentary portions of his own system, in which the veritable difficulty of the whole subject, the application to angles in space, had not even been attacked."

I shall leave the reader to judge of the accuracy of the general terms used in these passages in comparing the first "Ausdehnungslehre" with Hamilton's system as published in 1843 or 1844. The specific statements respecting Hamilton and Grassmann require an answer.

It must be Hamilton's "Theory of Conjugate Functions or Algebraic Couples," (read to the Royal Irish Academy 1833 and 1835, and published in vol. xvii. of the Transactions), to which reference is made in the statements concerning his "protracted study of Sets" and "mode of multiplying *couples*." But I cannot find anything like Grassmann's external or internal multiplication in this memoir, which is concerned, as the title pretty clearly indicates, with the theory of the complex quantities of ordinary algebra.

It is difficult to understand the statements respecting the "Ausdehnungslehre," which seem to imply that Grassmann's two kinds of multiplication were subject to some kind of limitation to a plane. The external product is not limited in the first "Ausdehnungslehre" even to three dimensions. The internal, which is a comparatively simple matter, is mentioned in the first "Ausdehnungslehre" only in the preface, where it is defined, and placed beside the external product as relating to directed lines. There is not the least suggestion of any difference in the products in respect to the generality of their application to vectors.

The misunderstanding seems to have arisen from the following sentence in Grassmann's preface: "And in general, in the consideration of angles in space, difficulties present themselves, for the complete (*allseitig*) solution of which I have not yet had sufficient leisure." It is not surprising that Grassmann should have required more time for the development of some parts of his system, when we consider that Hamilton, on his discovery of quaternions, estimated the time which he should wish to devote to them at ten or fifteen years (see his letter to Prof. Tait in the *North British Review* for September 1866), and actually took several years to prepare for the press as many pages as Grassmann had printed in 1844. But any speculation as to the questions which Grassmann may have had principally in mind in the sentence quoted, and the particular nature of the difficulties which he found in them, however interesting from other points of view, seems a very precarious foundation for a comparison of the systems of Hamilton and Grassmann as published in the years 1843–44. Such a comparison should be based on the positive evidence of doctrines and methods actually published.

Such a comparison I have endeavoured to make, or rather to indicate the basis on which it may be made, so far as systems of geometrical algebra are concerned. As a contribution to analysis in general, I suppose that there is no question that Grassmann's system is of indefinitely greater extension, having no limitation to any particular number of dimensions.

J. WILLARD GIBBS.

The Flying to Pieces of a Whirling Ring.

IN NATURE of May 14 (p. 31) I notice a letter by Mr. C. A. Carus-Wilson on the rotation of a hollow steel flask, composed apparently of a spherical shell mounted on an axis constituting a diameter. Mr. Carus-Wilson speaks of this body as being under a "tension" of "31·5 tons per square inch" at a certain speed of rotation. He does not, however, specify what is the tension to which he refers, nor where it is found, neither does he give the density and elastic constants of the material nor indicate the method by which he arrived at his result.

So far as I know, the only problem of the kind which has yet been solved is that of an isotropic spherical shell [1] rotating about an imaginary axis through its centre at speeds at which the strains follow Hooke's law. This differs from the case Mr. Carus-Wilson speaks of, inasmuch as the existence of a real material axis must introduce conditions somewhat different from those assumed by the mathematical theory, and further the results obtained by this theory cannot legitimately be applied to speeds exceeding that where bulging becomes sensible, if indeed so far.

This solution is probably, however, the nearest to the practical problem at present attainable.

According to it the strains and stresses vary throughout the shell with the distance from the centre, and the angular distance from the axis of rotation. They also depend on the density and on the elastic properties of the material. There are also at every point three principal stresses, whereof one it is true vanishes over the surfaces. Thus such a statement as Mr. Carus-Wilson's requires further explanation.

According to the two theories most commonly entertained, the quantity which determines the limiting safe speed is the maximum value of either the *greatest strain* or the *maximum stress-difference*,—*i.e.* the algebraical difference between the greatest and least principal stresses at a point. Over the surfaces of the shell the absolutely greatest values of both these quantities are found, for shells of all degrees of thickness, in the equatorial plane—or plane through the centre perpendicular to the axis of rotation.

Denoting the angular velocity by ω, the radii of the outer and inner surfaces respectively by a and a', the density by ρ, Young's modulus by E, the greatest strain by s, the maximum stress-difference by S, and the stress at right angles to the meridian plane by Φ, the three last quantities being measured in the equator, the following are some of the results I found for materials in which Poisson's ratio is 1/4:—

	$Es/\omega^2\rho a^2$		$S/\omega^2\rho a^2$		$\Phi/\omega^2\rho a^2$	
	Inner surface.	Outer surface.	Inner surface.	Outer surface.	Inner surface.	Outer surface.
$a'/a = 0·9$	0·950	0·833	1·064	0·866	0·912	0·866
$\frac{a-a'}{a}$ negligible	1·0	1·0	1·0	1·0	1·0	1·0

Apparently in the case mentioned by Mr. Carus-Wilson, $a'/a = 15/16 = 0·9375$. Supposing the material to have Poisson's ratio = 1/4, which seems to accord fairly with experiments on steel, the approximate values of s, S, and Φ, for this case could be obtained by interpolation from those I give above. The differences between the values of corresponding strains and stresses at the two surfaces are less, of course, for $a'/a = 15/16$ than for $a'/a = 0·9$, but still are far from negligible. Mr. Carus-Wilson's numerical result rather suggests that the tension he refers to is the stress Φ, measured as above in the equator, and that he employed the formula $\Phi = \omega^2\rho a^2$. This formula (see Cambridge Philosophical Transactions, vol. xiv. p. 300), is correct for the value of Φ in the *equator* in an *infinitely thin* shell, but it does not strictly apply to any shell whose thickness is comparable with its radius. In the paper in the Cambridge Transactions first referred to, there are given tables of the numerical measures of the strains and stresses over the surfaces for a series of values of a'/a for materials in which Poisson's ratio is 1/4. These give by interpolation fairly accurate values for all values of a'/a. For other values of Poisson's ratio, recourse must be had to the general formulæ given in the paper, unless $\epsilon, \equiv 1 - a'/a$, is very small, when the greatest values of s and S are given approximately by $Es/\omega^2\rho a^2 = 1 - \frac{1}{2}\epsilon(1 - \eta)$, $S/\omega^2\rho a^2 = 1 + \epsilon/(1 + \eta)$, where η is Poisson's ratio (see Camb. Trans., vol. xiv. p. 304).

A Comet observed from Sunrise to Noon.

A SHORT time ago I got the loan of an old number of *Harper's Monthly* (March 1889), good reading matter being very acceptable, however old, in this outlandish place, in which I read an article, on the origin of celestial species, by J. Norman Lockyer, F.R.S., Cor. Inst. France, that set me thinking of what I observed of the great comet of 1882, when it made its tremendous plunge round the sun, on September 18. At that time I was master of a small vessel, trading in the Society Islands; and on the day mentioned—in latitude 16° 25′ S., longitude 151° 57′ W. of Greenwich, a position about midway between the two islands Bolabola and Maupiti (the Maurua of Cook)—I saw, with the naked eye, the comet travel about 90° of the circle of the sun's disk, between sunrise and noon; but what made it most remarkable to us was that it should be possible for us, in a perfectly clear sky, to be able to watch it all, from sunrise to noon, with very little more distress to the eye than if in a clear night looking at a full moon.

Now, Sir, may it not be that this is partly a *proof* of the theory set forth by Norman Lockyer in the article above mentioned, viz. that comets are swarms of meteorites in collision, travelling through space, and that the outer invisible part of the swarm that formed this comet's nucleus had partially eclipsed the sun, like a veil over it? I am not aware if it was noticed by any competent astronomer or not, but the chances are that none had the splendid opportunity that we had to see the phenomena; so, Sir, knowing that men of science are always glad to get facts from observers in all parts of the world is my excuse for writing this to you, not knowing Mr. Lockyer's address. Thinking this, although late, may probably be of some interest to the scientific world, I leave you to do what you may think proper with it.

WM. ELLACOTT.

Raiatea, January 30.

Graphic Daily Record of the Magnetic Declination or Variation of the Compass at Washington.

I BEG to call your attention to the enclosed reprint from the May Pilot Chart of curves of magnetic declination as recorded at the United States Naval Observatory at Washington. This reprint admits of reproduction more readily than the curves as shown on the Pilot Chart, being in black and white, and only reduced to two-fifths of true size (the reduction on the Pilot Chart itself being one-quarter). It will be interesting to this Office to elicit expressions of opinion relative to the advantages of the prompt publication of these curves. The experiment is to be tried for three months, but it is not likely to be continued longer unless certain decided advantages develop. It may be of sufficient interest to NATURE to republish these curves, and thus assist us in giving them wide publicity.

RICHARDSON CLOOER,
Washington, D.C., May 6. Hydrographer.

[We are unable to print the curves, but we may note that they are issued with the following explanation:—"These curves indicate graphically the true direction in which the magnetic needle at the Naval Observatory pointed during each instant from noon, March 29, to noon, April 30. The base-line shows a slight break at the end of each two hours, 75th meridian time, and the amount of westerly variation at any time is 4° *plus* the number of minutes represented by the height of the curve above the base line at that time, measured by the scale at the right or left margin of the diagram. The slight breaks in the curve itself occur when the chronograph sheets are changed. Although the daily change of variation at any one place, even in magnetic storms such as those that have occurred during the past month, is too small to be of any importance in practical navigation, yet it is thought that the prompt publication of these curves cannot fail to interest masters of vessels, as well as scientific men. The mean daily curve, which can be drawn by taking the average of many such curves, shows that there is a regular, though slight, daily change in the variation, somewhat analogous to the daily range of the barometer, although the daily minimum of variation at Washington occurs at about 8 a.m., and the maximum between 1 and 2 p.m. It is proposed to continue the publication of these curves on this Chart for at least three months, and any questions regarding them will receive immediate consideration and reply. The attention of masters of vessels is called to the form issued by this Office for the record of observations of variation at sea, and to the general importance of the subject in connection with vessels' compasses and the variation curves plotted on our charts."]

The Alpine Flora.

IN connection with this subject (see NATURE, vol. xliii. p. 581) it may be well to draw the attention of botanists to the fact that a young vigorous strawberry plant, in an exposed garden, will, during the winter season, place all its leaves in a perfectly horizontal position, some even close to and resting on the ground, in striking contrast to its summer habit of erect growth, whereby it is often damaged by strong winds.

Whether direct climatal conditions be the sole cause of this peculiarity, or whether inherited, I cannot determine; presumably, in its natural surroundings, the continual crowding and consequent struggle would not necessitate the adoption of dwarfing as a means of survival. J. LOVEL.

May 13.

Magnetic Anomalies in Russia.

THE magnetic disturbances in England and Wales as communicated to NATURE, vol. xliii. p. 617, by M. Mascart and A. W. Rücker, are of great interest, but the size of the disturbances between Charkov and Kursk in Russia is of much higher value. More than 150 stations with magnetic elements have proved that in the above region there are points where the declination differs by 86°, the inclination by 29°, and the magnetic total force by 0·39 el. un. The principal centres are distant from each other not more than 12 kilometres. The m. elements are :—

Principal centres of disturbance.	Decl. °	Incl. °	Total force, e. u.
Nepchaevo	+ 48	+ 81	0·84
Visloe	− 33	+ 52	0·65
Kisselevo	− 38	+ 63	0·72
Sobinino	+ 30	+ 60	0·75
Petropavlovka	− 20	+ 76	0·80
Belgorod	− 36	+ 71	0·64

The normal values are − 1° Decl. ; + 64° Incl. ; 0·48 total force. The districts are covered by sedimentary rocks.

St. Petersburg, April 30. A. DE TILLO.

THE REJUVENESCENCE OF CRYSTALS.[1]

VERY soon after the invention of the microscope, the value of that instrument in investigating the phenomena of crystallization began to be recognized.

The study of crystal-morphology and crystallogenesis was initiated in this country by the observations of Robert Boyle; and since his day a host of investigators—among whom may be especially mentioned Leeuwenhoek and Vogelsang in Holland, Link and Frankenheim in Germany, and Pasteur and Senarmont in France—have added largely to our knowledge of the origin and development of crystalline structures. Nor can it be said with justice that this field of investigation, opened up by English pioneers, has been ignobly abandoned to others; for the credit of British science has been fully maintained by the numerous and brilliant discoveries in this department of knowledge by Brewster and Sorby.

There is no branch of science which is more dependent for its progress on a knowledge of the phenomena of crystallization than geology. In seeking to explain the complicated phenomena exhibited by the crystalline masses composing the earth's crust, the geologist is constantly compelled to appeal to the physicist and chemist; from them alone can he hope to obtain the light of experiment and the leading of analogy, whereby he may hope to solve the problems which confront him.

But if geology owes much to the researches of those physicists and chemists who have devoted their studies to the phenomena of crystallization, the debt has been more than repaid through the new light which has been thrown on these questions by the investigation of naturally-formed crystals by mineralogists and geologists.

In no class of physical operations is *time* such an important factor as in crystallization; and Nature, in producing her inimitable examples of crystalline bodies, has been unsparing in her expenditure of time. Hence it is not surprising to find that some of the most wonderful phenomena of crystallization can best be studied—some, indeed, can only be studied—in those exquisite specimens of Nature's handiwork which have been slowly elaborated by her during periods which must be measured in millions of years.

I propose to-night to direct your attention to a very curious case in which a strikingly complicated group of phenomena is presented in a crystalline mass: and these phenomena, which have been revealed to the student of natural crystals, are of such a kind that we can scarcely hope to reproduce them in our test-tubes and crucibles.

But if we cannot expect to imitate all the effects which have in this case been slowly wrought out in Nature's laboratory, we can, at least, investigate and analyze them; and, in this way, it may be possible to show that phenomena like those in question must result from the possession by crystals of certain definite properties. Each of these properties, we shall see, may be severally illustrated and experimentally investigated, not only in natural products, but in the artificially-formed crystals of our laboratories.

In order to lead up to the explanation of the curious phenomena exhibited by the rock-mass in question, the first property of crystals to which I have to refer may be enunciated as follows :-

Crystals possess the power of resuming their growth after interruption; and there appears to be no limit to the time after which this resumption of growth may take place.

It is a familiar observation that if a crystal be taken from a solution and put aside, it will, if restored after a longer or shorter interval to the same or a similar solution, continue to increase as before. But geology affords innumerable instances in which this renewal of growth in crystals has taken place after millions of years must have elapsed. Still more curious is the fact, of which abundant proof can be given, that a crystal formed by one method may, after a prolonged interval, continue its growth under totally different conditions and by a very different method. Thus, crystals of quartz, which have clearly been formed in a molten magma, and certain inclosures of glass, may continue their growth when brought in contact with solutions of silica at ordinary temperatures. In the same way, crystals of felspar, which have been formed in a mass of incandescent lava, may increase in size, when solvent agents bring to them the necessary materials from an enveloping mass of glass, even after the whole mass has become cold and solid.

It is this power of resuming growth after interruption, which leads to the formation of zoned crystals, like the fine specimen of amethyst enclosed in colourless quartz, which was presented to the Royal Institution seventy years ago by Mr. Snodgrass.

The growth of crystals, like that of plants and animals, is determined by their environment; the chief conditions affecting their development being temperature, rate of growth, the supply of materials (which may vary in quality as well as in quantity), and the presence of certain foreign bodies.

---

[1] The Friday Evening Discourse, delivered at the Royal Institution on January 30, 1891, by Prof. John W. Judd, F.R.S.

It is a very curious circumstance that the form assumed by a crystal may be completely altered by the presence of infinitesimal traces of certain foreign substances—foreign substances, be it remarked, which do not enter in any way into the composition of the crystallizing mass. Thus there are certain crystals which can only be formed in the presence of water, fluorides, or other salts. Such foreign bodies, which exercise an influence on a crystallizing substance without entering into its composition, have been called by the French geologists "mineralizers." Their action seems to curiously resemble that of diastase, and of the bodies known to chemists as "ferments," so many of which are now proved to be of organic origin.

Studied according to their mode of formation, zoned crystals fall naturally into several different classes.

In the first place, we have the cases in which the successive shells or zones differ only in colour or some other accidental character. Sometimes such differently coloured shells of the crystal are sharply cut off from one another, while in other instances they graduate imperceptibly one into the other.

A second class of zoned crystals includes those in which we find clear evidence that there have been pauses, or, at all events, changes in the rate of their growth. The interruption in growth may be indicated in several different ways. One of the commonest of these is the formation of cavities filled with gaseous, liquid, or vitreous material, according to the way the crystal has been formed—by volatilization, by solution, or by fusion; the production of these cavities indicating rapid or irregular growth. Not unfrequently it is clear that the crystal, after growing to a certain size, has been corroded or partially resorbed in the mass in which it is being formed, before its increase was resumed. In other cases, a pause in the growth of the crystal is indicated by the formation of minute foreign crystals, or the deposition of uncrystallized material along certain zonal planes in the crystal.

Some very interesting varieties of minerals, like the Cotterite of Ireland, the red quartz of Cumberland, and the spotted amethyst of Lake Superior, can be shown to owe their peculiarities to thin bands of foreign matter zonally included in them during their growth.

A curious class of zoned crystals arises when there is a change in the habit of a crystal during its growth. Thus, as Lavalle showed in 1851 (*Bull. Géol. Soc. Paris*, 2me. sér., vol. viii. pp. 610–13), if an octahedron of alum be allowed to grow to a certain size in a solution of that substance, and then a quantity of alkaline carbonate be added to the liquid, the octahedral crystal, without change in the length of its axes, will be gradually transformed into a cube. In the same way, a scalenohedron of calcite may be found inclosed in a prismatic crystal of the same mineral, the length of the vertical axis being the same in both crystals.

By far the most numerous and important class of zoned crystals is that which includes the forms where the successive zones are of different, though analogous, chemical composition. In the case of the alums and garnets, we may have various *isomorphous* compounds forming the successive zones in the same crystal; while, in substances crystallizing in other systems than the cubic, we find *plesiomorphous* compounds forming the different enclosing shells.

Such cases are illustrated by many artificial crystals, and by the tourmalines, the epidotes, and the felspars among minerals. The zones, consisting of different materials, are sometimes separated by well-marked planes; but in other cases they shade imperceptibly into one another.

In connection with this subject it may be well to point out that zoned crystals may be formed of two substances which do not crystallize in the same system. Thus, crystals of the monoclinic augite may be found surrounded by a zone of the rhombic enstatite; and crystals of a triclinic felspar may be found enlarged by a monoclinic felspar.

Still more curious is the fact that, where there is a similarity in crystalline form and an approximation in the dominant angles (plesiomorphism), we may have zoning and intergrowth in the crystals of substances which possess no chemical analogy whatever. Thus, as Senarmont showed in 1856, a cleavage-rhomb of the natural calcic carbonate (calcite), when placed in a solution of the sodic nitrate, becomes enveloped in a zone of this latter substance; and Tschermak has proved that the compound crystal thus formed behaves like a homogeneous one, if tested by its cleavage, by its susceptibility to twin lamellation, or by the figures produced by etching. In the same way, zircons, which are composed of the two oxides of silicon and zirconium, are found grown in composite crystals with xenotime, a phosphate of the metals of the cerium and yttrium groups.

These facts, and many similar ones which might be adduced, point to the conclusion that the beautiful theory of isomorphism, as originally propounded by Mitscherlich, stands in need of much revision as to many important details, if not, indeed, of complete reconstruction, in the light of modern observation and experiment.

The second property of crystals to which I must direct your attention is the following:—

If a crystal be broken, or mutilated in any way whatever, it possesses the power of repairing its injuries during subsequent growth.

As long ago as 1836, Frankenheim showed that, if a drop of a saturated solution be allowed to evaporate on the stage of a microscope, the following interesting observations may be made upon the growing crystals. When they are broken up by a rod, each fragment tends to re-form as a perfect crystal; and if the crystals be caused to be partially re-dissolved by the addition of a minute drop of the mother liquor, further evaporation causes them to resume their original development (*Pogg. Ann.*, Bd. xxxvii., 1836).

In 1842, Hermann Jordan showed that crystals taken from a solution and mutilated gradually became repaired or healed when replaced in the solution (*Müller Archiv. für* 1842, pp. 46–56). Jordan's observations, which were published in a medical journal, do not, however, seem to have attracted much attention from the physicists and chemists of the day.

Lavalle, between the years 1850 and 1853,[1] and Kopp, in the year 1855, made a number of valuable observations bearing on this interesting property of crystals (*Liebig Ann.*, xciv., 1855, pp. 118–25). In 1856 the subject was more thoroughly studied by three investigators who published their results almost simultaneously: these were Marbach (*Compt. rend.*, xliii., 1856, pp. 705–706, 800–802), Pasteur (*ibid.*, pp. 795–800), and Senarmont (*ibid.*, p. 799). They showed that crystals taken from a solution and mutilated in various ways, upon being restored to the liquid became completely repaired during subsequent growth.

As long ago as 1851, Lavalle had asserted that, when one solid angle of an octahedron of alum is removed, the crystal tends to reproduce the same mutilation on the opposite angle, when its growth is resumed! This remarkable and anomalous result has, however, by some subsequent writers been explained in another way to that suggested by the author of the experiment.

In the same way the curious experiments performed at a subsequent date by Karl von Hauer, experiments which led him to conclude that hemihedrism and other peculiarities in crystal growth might be induced by mutilation,[1] have been asserted by other physicists and chemists not to justify the startling conclusions drawn from them at the time. It must be admitted that new experiments bearing on this interesting question are, at the present time greatly needed.

---

[1] *Bull. Géol. Soc. Paris*, 2me sér., vol. viii. pp 610–13, 1851; Moigno, *Cosmos*, ii, 1853, pp. 454–56; *Compt. rend.*, xxxvi., 1853, pp. 493–95.

In 1881, Loir demonstrated two very important facts with regard to growing crystals of alum (*Compt. rend.*, Bd. xcii. p. 1166). *First*, that if the injuries in such a crystal be not too deep, it does not resume growth over its general surface until those injuries have been repaired. *Secondly*, that the injured surfaces of crystals grow more rapidly than natural faces. This was proved by placing artificially-cut octahedra and natural crystals of the same size in a solution, and comparing their weight after a certain time had elapsed.

The important results of this capacity of crystals for undergoing healing and enlargement, and their application to the explanation of interesting geological phenomena has been pointed out by many authors. Sorby has shown that, in the so-called crystalline sand-grains, we have broken and worn crystals of quartz, which, after many vicissitudes and the lapse of millions of years, have grown again and been enveloped in a newly formed quartz-crystal. Bonney has shown how the same phenomena are exhibited in the case of mica, Becke and Whitman Cross in the case of hornblende, and Merrill in the case of augite. In the felspars of certain rocks it has been proved that crystals that have been rounded, cracked, corroded, and internally altered—which have, in short, suffered both mechanical and chemical injuries—may be repaired and enlarged with material that differs considerably in chemical composition from the original crystal.

It is impossible to avoid a comparison between these phenomena of the inorganic world and those so familiar to the biologist. It is only in the lowest forms of animal life that we find an unlimited power of repairing injuries: in the Rhizopods and some other groups a small fragment may grow into a perfect organism. In plants the same phenomenon is exhibited much more commonly, and in forms belonging to groups high up in the vegetable series. Thus, parts of a plant, such as buds, bulbs, slips, and grafts, may—sometimes after a long interval—be made to grow up into new and perfect individuals. But in the mineral kingdom we find the same principle carried to a much farther extent. We know, in fact, no limit to the minuteness of fragments which may, under favourable conditions, grow into perfect crystals—no bounds as to the time during which the crystalline growth may be suspended in the case of any particular individual.

The next property of crystals which I must illustrate, in order to explain the particular case to which I am calling your attention to-night, is the following:—

Two crystals of totally different substances may be developed within the space bounded by certain planes, becoming almost inextricably intergrown, though each retains its distinct individuality.

This property is a consequence of the fact that the substance of a crystal is not necessarily continuous within the space inclosed by its bounding planes. Crystals often exhibit cavities filled with air and other foreign substances. In the calcite crystals found in the Fontainebleau sandstone, less than 40 per cent. of their mass consists of calcic carbonate, while more than 60 per cent. is made up of grains of quartz-sand, caught up during crystallization.

In the rock called "graphic granite," we have the minerals orthoclase and quartz intergrown in such a way that the more or less isolated parts of each can be shown, by their optical characters, to be parts of great mutually interpenetrant crystals. Similar relations are shown in the so-called micro-graphic or micro-pegmatitic intergrowths of the same minerals which are so beautifully exhibited in the rock under our consideration this evening.

There is still another property of crystals that must be kept in mind, if we would explain the phenomena exhibited by this interesting rock:—

A crystal may undergo the most profound internal changes, and these may lead to great modifications of the optical and other physical properties of the mineral; yet, so long as a small—often a very small—proportion of its molecules remain intact, the crystal may retain, not only its outward form, but its capacity for growing and repairing injuries.

Crystals, like ourselves, grow old. Not only do they suffer from external injuries, mechanical fractures, and chemical corrosion, but from actions which affect the whole of their internal structure. Under the influence of the great pressures in the earth's crust, the minerals of deep-seated rocks are completely permeated by fluids which chemically react upon them. In this way, negative crystals are formed in their substance (similar to the beautiful "ice-flowers" which are formed when a block of ice is traversed by a beam from the sun or an electric lamp), and these become filled with secondary products. As the result of this action, minerals, once perfectly clear and translucent, have acquired cloudy, opalescent, iridescent, avanturine, and "schiller" characters; and minerals, thus modified, abound in the rocks that have at any period of their history been deep-seated. As the destruction of their internal structure goes on, the crystals gradually lose more and more of their distinctive optical and their physical properties, retaining, however, their external form; till at last, when the last of the original molecules is transformed or replaced by others, they pass into those mineral corpses known to us as "pseudomorphs."

But while crystals resemble ourselves in "growing old," and, at last, undergoing dissolution, they exhibit the remarkable power of growing young again, which we, alas! never do. This is in consequence of the following remarkable attribute of crystalline structures:—

It does not matter how far internal change and disintegration may have gone on in a crystal—if only a certain small proportion of the unaltered molecules remain, the crystal may renew its youth and resume its growth.

When old and much-altered crystals begin to grow again, the newly-formed material exhibits none of those marks of "senility" to which I have referred. The sand-grains that have been battered and worn into microscopic pebbles, and have been rendered cloudy by the development of millions of secondary fluid cavities, may have clear and fresh quartz deposited upon them to form crystals with exquisitely perfect faces and angles. The white, clouded, and altered felspar-crystals may be enveloped by a zone of clear and transparent material, which has been added millions of years after the first formation and the subsequent alteration of the original crystal.

We are now in a position to explain the particular case which I have thought of sufficient interest to claim your attention to-night.

In the Island of Mull, in the Inner Hebrides, there exist masses of granite of Tertiary age, which are of very great interest to the geologist and mineralogist. In many places this granite exhibits beautiful illustrations of the curious intergrowths of quartz and felspar, of which I have

[1] *Wien. Sitz. Ber.*, xxxix., 1860, pp. 611–22; Erdmann, *Journ. Prakt. Chem.*, lxxxi. pp. 356–62; *Wien. Geol. Verhandl.*, xii. pp. 212–13, &c.; Frankenheim, *Pogg. Ann.*, cxiii. 1861. Compare Fr. Scharff, *Pogg. Ann.*, cix., 1860, pp. 529–38; *Neues Jahrb. für Min.*, &c., 1876, p. 24; and W. Sauber, *Liebig Ann.*, cxxiv., 1862, pp. 78–82; also W. Ostwald, "Lehrbuch d. Allg. Chem.," 1885, Bd. i. p. 738; and O. Lehmann, "Molekular Physik.," 1888, Bd. i. p. 312.

already spoken. Such parts of the rock often abound with cavities (druses), which I believe are not of original but of secondary origin. At all events, it can be shown that these cavities have been localities in which crystal growth has gone on—they constitute indeed veritable laboratories of synthetic mineralogy.

Now, in such cavities the interpenetrant crystals of quartz and felspar in this rock have found a space where they may grow and complete their outward form; and it is curious to see how sometimes the quartz has prevailed over the felspar and a pure quartz-crystal has been produced; while at other times the opposite effect has resulted, and a pure felspar individual has grown up. In these last cases, however much the original felspar may have been altered (kaolinized and rendered opaque), it is found to be completed by a zone of absolutely clear and unaltered felspar-substance. The result is that the cavities of the granite are lined with a series of projecting crystals of fresh quartz and clear felspar, the relations of which to the older materials in an altered condition composing the substance of the solid rock, are worthy of the most careful observation and reflection.

Those relations can be fully made out when thin sections of the rock are examined under the microscope by the aid of polarized light, and they speak eloquently of the possession by the crystals of all those curious peculiarities of which I have reminded you this evening.

By problems such as those which we have endeavoured to solve to-night, the geologist is beset at every step. The crust of our globe is built up of crystals and crystal fragments—of crystals in every stage of development, of growth, and of variation—of crystals undergoing change, decay, and dissolution. Hence the study of the natural history of crystals must always constitute one of the main foundations of geological science; and the future progress of that science must depend on how far the experiments carried on in laboratories can be made to illustrate and explain our observations in the field.

BRITISH INSTITUTE OF PREVENTIVE MEDICINE.

A VIGOROUS attempt is being made by ignorant and prejudiced persons to prevent the establishment of a National Hygienic Institute worthy of the United Kingdom. A deputation will wait upon Sir Michael Hicks-Beach, President of the Board of Trade, on Friday, June 5, to submit to him an exact statement of the facts relating to the matter. Meanwhile, the Executive Committee has issued the following circular:—

On Monday afternoon, July 1, 1889, a meeting was held at the Mansion House, under the Presidency of Sir James Whitehead, Bart., then Lord Mayor of London, "for the purpose of hearing statements from Sir James Paget, and other representatives of scientific and medical opinion, with regard to the recent increase of rabies in this country, and the efficacy of the treatment discovered by M. Pasteur for the prevention of hydrophobia."

Although convinced of the advantages likely to accrue to the community at large by the founding of a Bacteriological Institute in England, the Committee felt that the time was not then come for establishing in England an institute similar to the "Institut Pasteur" in Paris, or the "Hygienische Institut" in Berlin. The idea, however, was not abandoned, and on December 5, 1889, an Executive Committee was appointed to take measures for the purpose of establishing in England a British Institute of Preventive Medicine.

Acting on the advice of their solicitors, Messrs. Hunters and Haynes, the Executive Committee decided to incorporate the Institute as a limited liability company, with the omission of the word "Limited," in order to impress the public with the fact that the Institute was not established for purposes of gain, but for purely charitable and scientific objects.

The application was lodged at the Board of Trade on February 13, 1891, and, shortly afterwards, a number of petitions were sent in asking the Board of Trade to withhold its license, as the objects of the Institute "clearly pointed to experiments on living animals." As Chairman of the Committee, Sir Joseph Lister then wrote to the President of the Board of Trade, showing why, in the opinion of the Committee, their opponents should not gain their point. In the first place, he pointed out that the granting of a vivisection license is not within the province of the Board of Trade, but under the control of the Secretary of State for the Home Department. In the second place, he clearly proved that it is absolutely necessary that the Institute should be licensed in the manner described, for it could not be registered under the Companies Act, 1862, without most seriously interfering with its prospects. From counsel's opinion it is evident that, should the Institute be registered as an ordinary limited liability company under the Act, it would at any time be possible for the members to wind up the company and divide the funds of the Institute; whereas the Board of Trade, in granting the license asked for, would make it a condition that all the property of the Institute should be applied to the advancement of science and kindred subjects only, and not be distributed among the members. In this way only could security be given that the funds would be applied for the purposes intended.

This letter was posted by one of the secretaries on May 12, 1891; but on the same day the solicitors to the Executive Committee received a letter from the President of the Board of Trade, who, without giving any reason whatever for his decision, declined to grant the application. On the next day, however, Sir Joseph Lister received a letter in answer to that posted on May 12, in which the President of the Board of Trade intimated his willingness to receive a deputation on June 5 at 11 a.m.

Workers in bacteriological science are now labouring under considerable difficulties, as there is no place in the United Kingdom specially fitted for such research. By the establishing of this Institute, they would be placed in the best possible conditions for carrying out original investigations. Moreover, a central Institute for the systematic teaching of bacteriology would be provided, not only for medical men, but also for veterinary surgeons, chemists, agriculturists, &c.

At present, in spite of the efforts made in this direction by several medical schools, most of the English workers who wish to gain special knowledge in bacteriology, are compelled to go to the Continental laboratories for their instruction. The question, therefore, which the Board of Trade will have to decide is, whether such a state of things should continue, or whether England should have its own national bacteriological Institute. Similar Institutes have been endowed by the State in other countries; and the Board of Trade, by refusing to grant their application, would prevent a body of private gentlemen from doing what has been done at great expense by the Governments of other nations.

NOTES.

We are informed that Kew has recently acquired by purchase from Mr. F. Curtis, a descendant of William Curtis, the founder of the *Botanical Magazine*, about 1650 original drawings, chiefly of figures which appeared in that publication. They belong partly to the first series and partly to the second, from 1800 to 1826—that is to say, during the period that the magazine was edited by Dr. Sims. Many of these drawings are very beautiful, and very carefully coloured, especially those done by James

Sowerby and Sydenham Edwards; but some of the finest of their work was not reproduced in the plates. The collection also includes some of the poorest work that ever appeared in the magazine. In 1815 Sydenham Edwards seceded, and worked for the rival *Botanical Register;* Sowerby had ceased contributing, and there seems to have been a lack of novelties for illustration. Towards the end of Dr. Sims's editorship, in 1826, the *Botanical Magazine* was doubtless supplanted in a great measure by the *Botanical Register* then conducted by the vigorous Lindley. Its circulation greatly decreased, and the impression was small; hence this series is very rare. The following year, however, Sir William Hooker became editor and speedily raised both the artistic and botanical character of the magazine. Many of the plates published during the latter half of Dr. Sims's editorship are not signed, but all the drawings are, and we learn that William Hooker, the artist of the *Paradisus Londinensis*, was an occasional contributor. The collection also contains a number of unpublished drawings.

A LETTER lately received from Emin Pasha by one of his ornithological correspondents in Europe is dated from one of the larger islands on Lake Victoria Nyanza in November last. It is full of details about birds, in which, as is well known, the Pasha takes the keenest interest, and alludes especially to an apparently new *Gralline* form, with three toes, met with in that district. Emin was on the point of starting southwards into the territory near the north end of Lake Tanganyika, and is now probably somewhere in that little-known country. He had been joined by Dr. Stuhlman, a young naturalist of Hamburg. Dr. G. Hartlaub, of Bremen, has just published a memoir on the birds collected by Emin during his return to the coast with the Stanley Expedition, and his subsequent sojourn at Bagamoyo. The specimens are referred to 140 species, of which eight are described as new to science.

THE Council of the Institution of Naval Architects has resolved to award the gold medal of the Institution to Prof. V. B. Lewes for his paper on boiler deposits, read at the Institution's recent annual general meeting.

THE President of the Royal Society, who is Chairman of the Board of Visitors, will hold the annual visitation of the Royal Observatory at Greenwich on Saturday, June 6 next. The Observatory will be open for inspection at 3 p.m.

MR. JAMES E. KEELER, the Astronomer of the Lick Observatory, has lately been appointed Director of the Alleghany Observatory, in succession to Mr. S. P. Langley, Secretary of the Smithsonian Institution.

A CZECH Academy of Sciences was opened at Prague on the 18th inst., by the Archduke Charles Louis. The Latin title of the Academy is Bohemica Scientiarum, litterarum et artium Academia Imperatoris Francisci Josephi; the President is Josef Hlávka, and the General Secretary Dr. F. J. Studnička.

AN extra evening meeting of the Royal Institution will be held on Tuesday, June 2, at nine o'clock, when Dr. Charles Waldstein will give a discourse on the discovery of "The Tomb of Aristotle."

AMERICAN papers announce the death of Prof. J. E. Hilgard, late superintendent of the U.S. Coast Survey. He was born at Zweibrücken in 1825, went to America with his father in 1835, and entered the service of the U.S. Coast Survey in 1845. "His work," says the New York *Nation*, "lay directly in the line of his profession, in the improvement of methods, the determination of weights and measures, and the novel method of ascertaining the differences of longitude by telegraph. His publications on these subjects are to be found chiefly in the Coast Survey Reports. One of the most noteworthy relates to the telegraphic determination of the differences of longitude between Greenwich, Paris, and Washington. He was a delegate to the International Metric Commission in 1872, and a member of the International Bureau of Weights and Measures, of which he declined the directorship. He was an original member of the National Academy of Sciences, and for some years its Home Secretary. In 1874 he was elected President of the American Association for the Advancement of Science. He succeeded to the work of Bache in connection with the work of the Bureau of Weights and Measures, and took a leading part in preparing exact metric standards for distribution to the States and Territories."

THE recent botanical mission of Mr. D. Morris to the West Indies forms the subject of the *Kew Bulletin* for May and June. The *Bulletin* publishes the official correspondence recording the circumstances under which the Imperial Government assented to Mr. Morris's mission, and reproduces his report to the Secretary of State for the Colonies.

THE *Kew Bulletin* does good service by publishing lists of garden plants annually described in botanical and horticultural publications, both English and foreign. In Appendix II., 1891, there is a list which comprises all the new introductions recorded during 1890. "These lists," says the *Bulletin*, "are indispensable to the maintenance of a correct nomenclature, especially in the smaller botanical establishments in correspondence with Kew, which are, as a rule, only scantily provided with horticultural periodicals. Such a list will also afford information respecting new plants under cultivation at this establishment, many of which will be distributed from it in the regular course of exchange with other botanic gardens."

ON the 13th inst. the Council of the county borough of Bootle decided to appropriate and set aside for the purpose of technical education the whole of the portion of the Exchequer contribution account which may so be used under the provision of the Local Taxation (Customs and Excise) Act, 1890. The Free Library and Museum Committee were entrusted with the carrying out of a scheme submitted by them to the Council; and they have appointed Mr. John J. Ogle to the office of Organizing Secretary to the Bootle Technical School. Mr. C. H. Hunt was also appointed Registrar. The sum available is estimated at £1936 per annum.

THE following is an extract from the *Times* of last week which may interest many of our readers:—Some months ago a company, which had been formed at Wheeling, West Virginia, for the purpose of "developing" that city, began to drill a well in search of petroleum or natural gas. A depth of over 4100 feet was reached, and in this distance a dozen thick veins of coal are said to have been passed, while petroleum and gas have both been struck—though not in paying quantities—and gold quartz, iron ore, and many other minerals have been brought to the surface. The officers of the Geological Survey at Washington, according to a Wheeling despatch, have become very interested in the proceeding, and "the hole will be drilled to a depth of one mile." After this the Government will take up the work under the direction of two expert officers of the Survey, and the drilling will be continued into the earth as far as human skill can penetrate. The object is to ascertain the thermometric and magnetic conditions as far as possible.

THE Transandine Railway across the Andes, connecting the Argentine railway system with that of Chili, has been the subject of an interesting article in *Engineering*. Our contemporary in its issue of this week again deals with this fine piece of engineering, and describes the tunnelling plant used, as well as the distribution by electrical means of the power available and necessary for driving the air compressors for the Ferroux rock drills used. This line across the Andes consists of a series of tunnels and other heavy works; the tunnels had to be bored in most inaccessible regions, where the means of transport are meagre in the extreme. The whole of the plant therefore had to be designed with great care and with special reference to the unusual requirements. Weight had to be minimized, and strength and simplicity had to be carefully obtained. Water-power was available at some distance from the scene of operations; the water-power was brought to the primary stations by means of 20-inch steel pipes. On the Chilian side the primary station contained ten dynamos and two spare ones, each being of 80 horse-power, and each coupled direct to, and driven by, a Girard turbine. The electric power generated is transmitted through a cable to secondary stations, where, by means of motors, the air-compressors are operated. A similar arrangement is in use on the Argentine side, only the dynamos are of 40 horse-power, because they had to be transported over mountains on mules' backs, which made it necessary to minimize the weight. This use of the electrical transmission of power is highly interesting, the circumstances being such that, without it, the boring of the tunnels would have been a work of great expense and magnitude.

Globus has received information from Japan to the effect that there is an increasing reaction in the country against foreign influences. This is said to be especially visible in schools where European instruction is given. Two such schools, one of which formerly had 300 pupils, the other 150, have been obliged to combine their forces, having no more than 150 pupils between them. At the University of Tokio the number of native lecturers increases, while that of the foreign staff decreases.

IN the New York *Sun*, Mr. G. F. Kunz, the well-known expert in gems, has recently called attention to a property of the diamond which may serve as a means of distinguishing it from other substances. Referring to the paper of Robert Boyle "On a Remarkable Diamond that Shines in the Dark," published in the Transactions of the Royal Society in 1663, Mr. Kunz remarks that this paper has been indirectly alluded to by a number of authors, but never read. Among a quantity of facts Boyle mentions one diamond that phosphoresced simply by the heat of the hand, absorbed light by being held near a candle, and emitted light on being rubbed. He stated that many diamonds emitted light by being rubbed in the dark. The experiments made by Mr. Kunz show conclusively not only that Boyle's statement that some diamonds phosphoresce in the dark after exposure to the sunlight or an arc of electric light is true, but also that all diamonds emit light by rubbing them on wood, cloth, or metal, a property which will probably prove of great value in distinguishing between the diamond and other hard stones, as well as paste, none of which exhibit this phenomenon, and will be welcomed by the general public who do not possess the experience of the dealer in diamonds. The property is evidently not electric, or it would not be visible on being rubbed on metal.

WE learn from the *American Meteorological Journal* for April that the appropriation for the new Weather Service of the United States is 879,753 dollars, being an increase of 62,797 dollars on the amount for the current year. This is accounted for by the addition of 50,000 dollars for the proposed extension of the service in agricultural regions, and by the fact that, under the present arrangement, five of the leading officials were assigned from the army, and their salaries must henceforward be provided for from the appropriation for the new Weather Service. The Chief of the Service is to receive 4500 dollars a year. No appointment has yet been made to this position. It is quite possible that the present Chief Signal Officer will be detailed from the army for this duty, and Prof. Abbe, Prof. W. M. Davis, Prof. Nipher, and Dr. Hinrichs are some of the other prominent meteorologists mentioned as possible candidates. The same *Journal* also reports that Dr. Baker, Secretary of the Michigan State Board of Health, has investigated the cause of influenza. He stated that the germs are at all times present, but that there must be certain coincident meteorological conditions to irritate the throat and air passages sufficiently to let the germ gain an entrance to the body. These conditions were, in this instance, the excessive prevalence of north and north-east winds, and the excessive amount of ozone during the past three months.

MR. C. L. WRAGGE has issued a circular, dated February 3 last, stating that "in consequence of the rapid extension of the Meteorological Service of Australasia in connection with the Queensland Government—an extension which now embraces a large portion of the Western Pacific Ocean, New Guinea, and the Malay Archipelago—it has been determined to stop the issue of the large charts which have hitherto dealt with the meteorology of Australasia only, and to issue, instead, in the early future, a weather chart as complete as possible, embracing not only Australasia, but also the regions above indicated." Some charts have already been issued giving the isobaric lines for the region referred to, and extending southwards and eastwards to New Zealand and the New Hebrides. Isobars drawn for 20° to 30° to the eastward of Brisbane must be to a great extent problematical, and in fact this is admitted by the broken lines extending over the ocean. The information, to say the least, seems at present insufficient for the purpose, and over large tracts it is absolutely wanting; but the establishment of stations in remote islands is, of itself, very desirable.

THE other day Prof. Vambéry delivered in Edinburgh, under the auspices of the Royal Scottish Geographical Society, an interesting lecture on British civilization and influence in Asia. He had many pleasant things to say about England, but did not quite overlook her shortcomings. He said he was immensely struck by the indifference shown by the public at large to everything that concerned Asia. He had lectured in more than 20 towns in this country, and found, even amongst the middle classes, great ignorance in regard to Asiatic geography and ethnography. Asiatic languages, moreover, were greatly neglected. Germany, which had not got any territory in Asia, bestowed far greater attention upon the old world than this country. He opined that if the interest in Asia would increase in this country commensurately with its political power and influence over the various races in Asia, Britain would decidedly remain there a permanent Power which could never be ousted by any rival. He thought that there ought to be more schools for Oriental languages in this country. There was a general supposition that Britons in general could not learn foreign languages, but that was not true. The greatest linguists of our age had been British, as, for example, Lord Strangford for Turkish, and the late Sir Richard Burton and the late Prof. Palmer for Arabic. Then there were scholars like Sir James Redhouse, Sir Henry Rawlinson, Sir William White, and many others bearing evidence of the brilliant linguistic capacity of the British. He believed that nothing could be easier than to recruit in this island a goodly number of Oriental linguists for employment in various Asiatic countries.

A PAPER by Messrs. G. F. Harris and H. W. Burrows, on the Eocene and Oligocene beds of the Paris Basin, is to be issued as a separate publication by the Geologists' Association. It will be illustrated by a map and sections. The paper is the result of several years' careful study of the Parisian Tertiaries, and close communication with many eminent French geologists. The authors give an elaborate appendix, consisting of a list of the fossil Mollusca, some 3500 species, showing the range in time; the nomenclature of each species has been critically revised and brought up to date. Careful attention has also been paid to the relationship between recent and Tertiary forms. The generic names under which most of the shells are still known in this country are added as an assistance to the student.

THE Physical Society of London has published the first part of the eleventh volume of its Proceedings. Among the contents are notes on photographs of rapidly moving objects, and on the oscillating electric spark, by Mr. C. V. Boys; a formula for calculating approximately the self-induction of a coil, by Prof. John Perry; a lecture experiment illustrating the effect of heat upon the magnetic susceptibility of nickel, by Mr. Shelford Bidwell; and experiments in photo-electricity, by Prof. G. M. Minchin.

A LECTURE by Prof. A. Macalister, delivered on January 29, on the opening of the new anatomical lecture-room at Cambridge, has been published by the Cambridge University Press. The subject is "The History of the Study of Anatomy in Cambridge."

MESSRS. CHARLES GRIFFIN AND CO. have published the eighth annual issue of the "Year-book of the Scientific and Learned Societies of Great Britain and Ireland." The work is compiled from official sources, and comprises lists of the papers read during 1890 before Societies engaged in fourteen departments of research, with the names of their authors.

THE Engineering Company, publishers, New York, are issuing a new monthly magazine, entitled *Engineering*, which is to be wholly devoted to the record of industrial progress. The first two numbers have been published.

THERE are some valuable morphological notes in the Johns Hopkins University Circulars for May. Among other papers we may mention one on the structure and development of the gonophores of a certain Siphonophore belonging to the order Auronectæ (Haeckel), by W. K. Brooks and E. G. Conklin. Other papers are: preliminary notes on some new species of Squilla, by R. P. Bigelow, and a preliminary note on the anatomy and transformation of Tornaria, by T. H. Morgan.

THE "Bibliothèque Évolutioniste" is the general title of a new scientific series which is being published in Paris. The editor is M. Henry de Varigny. The first volumes are mostly translations, Wallace's "Darwinism" opening the list; but French authors are also to contribute, and works are being prepared by Messrs. A. Sabatier, of Montpellier; J. Deniker, the well-known anthropologist; Prof. Giard, and others.

IN NATURE for May 14, p. 36, line 5 from top, or "1887" read "1889."

A NEW and very beautiful silver mineral is described by Mr. F. A. Genth in the May number of the *American Journal of Science*. It was discovered by Señor Aguilar, of the San Carlos Silver Mine at Guanajuato, Mexico, and has been named after him, aguilarite. It is a sulpho-selenide of silver, of the composition $Ag_2S + Ag_2Se$, the analyses of pure crystals agreeing exactly with this formula. The crystals are iron-black in colour, and possess a most brilliant lustre. They belong to the cubic system, and consist of curious skeleton dodecahedrons, the edges of which are perfect, while the centres of the faces are more or less worn or imperfectly developed. These dodecahedrons are frequently elongated in such a manner as to resemble either tetragonal prisms terminated by pyramids of the opposite order, or hexagonal prisms terminated by rhombohedral planes. They generally occur in interlaced and closely aggregated groups, the individual crystals of which attain a size of a centimetre or more in diameter. They are for the most part embedded in colourless calcite, which may readily be removed from them by means of dilute acetic acid; frequently a little quartz is associated with them. The crystals are readily sectile and malleable, and their hardness is only 2·5. Their specific gravity is 7·586. When heated in an open tube to low redness, gradually increasing to bright redness, they yield metallic silver, together with a slight sublimate of selenium, and slender needles of selenious and sulphuric oxides, which latter forms, with a little of the silver, silver sulphate. In many of the specimens of aguilarite examined, the crystals were observed to be penetrated in a remarkable manner by round holes, and they also frequently exhibited deposits of pure metallic silver upon their faces.

SEVERAL of the simpler sulphides of the organic radicles have been found to occur naturally in the crude petroleum oil of Ohio by Messrs. Mabery and Smith, who describe the mode adopted for their isolation in the current number of the *American Chemical Journal*. As far as they are aware, these alkyl sulphides have never previously been found in nature. When the higher boiling fractions of the distilled oil are agitated with oil of vitriol, these sulphur compounds are taken up by the sulphuric acid, and, upon subsequently neutralizing the acid solution with slaked lime, unstable calcium salts are obtained, which are readily decomposed by distillation in steam, which carries over the sulphides without decomposition. By employing these reactions upon a large scale, and afterwards subjecting the mixed sulphides to a rigorous fractional distillation under reduced pressure (150 mm. being the most convenient working pressure), the following sulphides have been isolated: methyl sulphide, $(CH_3)_2S$; ethyl sulphide, $(C_2H_5)_2S$; normal propyl sulphide, $(C_3H_7)_2S$; normal and iso-butyl sulphides, $(C_4H_9)_2S$; amyl sulphide, $(C_5H_{11})_2S$; hexyl sulphide, $(C_6H_{13})_2S$; and a few other sulphides of mixed radicles. Most of these sulphides were obtained in the pure state by treating the products of the fractionation with mercuric chloride, and thus obtaining crystals of the addition compounds of the type $(CH_3)_2S \cdot HgCl_2$, and subsequently decomposing these crystals of the mercury compounds with sulphuretted hydrogen.

THE additions to the Zoological Society's Gardens during the past week include a Barbary Ape (*Macacus inuus* ♂) from North Africa, presented by the Rev. G. H. Watkins; a Diuca Finch (*Diuca grisea*), two Gay's Finches (*Phrygilus gayi*) from Chili, two De Filippi's Meadow Starlings (*Sturnella defilippi*) from La Plata, presented by Mr. Charles G. Sharpe; two Bankiva Jungle Fowls (*Gallus bankiva* ♂ ♀) from India, presented by Captain George James; a Common Rhea (*Rhea americana*) from South America, presented by Mr. R. P. Houston; an Algerian Tortoise (*Testudo mauritanica*) from North Africa, presented by Mrs. Margaret Clarke; a Black-eared Marmoset (*Hapale penicillata*) from South-east Brazil, presented by Mr. Aubrey Lace; a Capybara (*Hydrochœrus capybara*), a Brown Milvago (*Milvago chimango*), a Violaceous Night Heron (*Nycticorax violaceus*) from South America, two Blue-bearded Jays (*Cyanocorax cyanopogon*) from Para, four Crested Screamers (*Chauna chavaria*) from Buenos Ayres, deposited; two Variegated Sheldrakes (*Tadorna variegata*) from New Zealand, two Larger Tree Ducks (*Dendrocygna major*) from India, purchased; two Japanese Deer (*Cervus sika* ♂ ♀), a Chinchilla (*Chinchilla lanigera*), an African Wild Ass (*Equus tæniopus*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE DRAPER CATALOGUE OF STELLAR SPECTRA.—Vol. xxvii. of the *Annals of the Astronomical Observatory of Harvard College* contains a catalogue of the spectra of 10,351 stars, nearly all of them north of the parallel of declination − 25°, photographed with the 8-inch Bache telescope. As the work forms a part of the Henry Draper Memorial, it is suggested that it be designated as the Draper Catalogue. In order to produce the spectra, a prism 8 inches square and having a refracting angle of 13°, was fastened in front of the object-glass, with its refracting angle placed perpendicular to the earth's axis. The spectra obtained have been conveniently arranged in classes indicated by the letters A to Q. Of these, A, B, C, and D indicate varieties of Secchi's first type, E to L varieties of the second type, M the third type, and N the fourth type. The letter O is used for stars whose spectra consist mainly of bright lines, and the letter P is reserved for planetary nebulæ. The classes O and P closely resemble each other, and are regarded by Prof. Pickering as a fifth type of spectrum. All spectra not included in these classes are indicated by the letter Q. Viewed as the result of a preliminary survey of the types of the photographic spectra of stars, the catalogue is of the highest importance. But it is to the discussion of individual lines, which is to follow in another volume, that we have to look for detailed information which may improve our knowledge of stellar constitution.

SOLAR OBSERVATIONS FROM JANUARY TO MARCH 1891.—In *Comptes rendus*, No. 19 (May 11, 1891), Prof. Tacchini gives the following account of solar activity during the first three months of this year.

Observations of spots and faculæ have been made on 64 days, viz. 16 in January, 26 in February, and 22 in March. The results obtained are :—

1891.	Relative frequency		Relative magnitude		Number of groups per day.
	of spots.	of days without spots.	of spots.	of faculæ.	
January	1·56	0·30	18″·50	16″·88	1·38
February	2·31	0·15	24·04	89·62	2·38
March	1·27	0·14	11·91	41·82	1·45

The following are the results of observations of hydrogen prominences :—

1891.	Number of days of observation.	Prominences		
		Mean number.	Mean height.	Mean extension.
January	13	4·62	36″·9	1°·3
February	22	7·55	44·1	1·8
March	17	6·12	40·1	1·5

When these numbers are compared with those obtained for the last three months of 1890, a marked increase is apparent. In addition to this the results obtained for spots, faculæ, and prominences indicate that a secondary maximum of solar activity occurred during the month of February.

THE CONSTANT OF ABERRATION.—A short time ago MM. Lœwy and Puiseux described the principle of their new method of studying annual aberration and the general conclusions deduced from the observations made last year (see NATURE, vol. xliii. p. 498). In *Comptes rendus*, No. 20 (May 19) they give a detailed account of the *modus operandi*, and the numerical values obtained by the observation of two groups of four stars. The mean of all the observations gives for the constant of aberration the value 20″·447 ± 0″·024.

ANIMAL LIFE ON A CORAL REEF.[1]

IN nearly all the shallow waters of the tropical seas there is an abundant fauna, but nowhere is there such a crowd of marine animals of all kinds as there is in the region that extends from the growing edge of the coral reef to a depth of some 10 or 15 fathoms beyond it. This may be due to the fact that in this region there is plenty of light and heat, no great or sudden changes of temperature, or of the chemical composition of the water, and there is an abundant food supply brought by tidal currents from the surface of the ocean. Here it is, then, that we find the richest fauna. Here it is that the struggle for existence is most severe, and here it is that the animals are protected and concealed by the most pronounced marks and colours, and provided by Nature with various forms of armour, stings and spines to defend them in the battles with their enemies.

One of the most interesting results of this severe struggle for existence, or perhaps it would be more correct to say of the large number of species competing for existence, is the important faunistic difference that may be observed between one reef and another—nay, indeed, between one part of a reef and another part of the same reef.

Darwin long ago pointed out that in the struggle for existence a very slight advantage gained by any one of the competing species may entirely alter the whole aspect of the field ; and it follows that a very slight though constant difference in the physical conditions, such, for example, in the case of coral reefs, as rapidity of tidal currents, amount of surf or character of the shore rocks, may completely change the characteristics of the fauna. There are, it is true, some genera and species that are apparently found on all the reefs, such as Tubipora and Madrepora, but every reef has its own peculiar characters, and a naturalist never feels when he is examining one that he has seen something exactly like it on any previous occasion.

The majority of the corals that are found on the reefs of North Celebes belong to two great orders—the Zoantharia and Alcyonaria. The prevailing colour of the living Zoantharia is dull greeny-brown. The tentacles and the oral disks, and in some cases the growing or younger branches as a whole, may be very brightly coloured. White, pink, emerald green, violet, and blue, are colours frequently met with in different parts of the Zoantharian colony. The colours of the Alcyonarians may be due to the bright red, yellow, or purple spicules, or to the rich brown or green colour of the soft parts. There is very considerable variation in the colour of the soft parts of the Alcyonaria. The tentacles of the polyps of Tubipora, for example, may be any shade between bright green and pinkish-brown. A species of Sarcophytum, again, common on the shores of Celebes, showed green and greenish-yellow and yellow examples within the same half-mile of reef. All of these coral colours, with the exception of the colour of the spicules mentioned above, are soluble in spirit, the soft parts becoming, after prolonged immersion in this fluid, pale brown. The alcohol extracts of a considerable number of corals have now been submitted to spectrum analysis, and the bands they exhibit show close affinities with vegetable chlorophyll.

There is no experimental evidence at present that proves that the colours of the corals, nor, indeed, of the sponges, are either protective or warning in function. It seems much more probable that these brilliant colours represent different stages in the building up or breaking down of some complex chemical substance that is always present in marine zoophytes, and performs some important physiological function.

Besides the numerous sponges, corals, holothurians, mollusks, &c., that are attached to the bottom or creep but slowly from place to place, the numerous species of swimming animals that are capable of active movements in pursuit of prey, or escaping from their enemies, must be considered as part of the fauna of the coral reef. These include fishes, cephalopods, and crustacea, and those of them that seem to live habitually among the corals of the reef are characterized by the possession of very curious spots or stripes and very brilliant colours.

Soon after my arrival in Talisse a large lobster was brought to me marked by broad transverse bands of blue and white ; a large Squilla is not uncommon marked with similar bands of white and deep purple, and the little prawn *Stenopus hispidus*, that I found in a tidal pool close to a reef, has bands of red and white. The cephalopods have also peculiar markings. One specimen that I found, *Octopus lunulatus*, had large blue spots over its body and arms. The fishes, again, are marked with spots and stripes of various kinds and many brilliant colours.

Without going too deeply into the argument, we are justified in saying that these animals are so marked and coloured because they live among the brilliant surroundings of the coral reef ; or, to put it in another way, animals similarly organized and of similar habits would be at a disadvantage on the coral reefs if they were not so marked and coloured. The other fishes of the tropics do not possess these curious and beautiful characters ; the sharks, bonitos, flying fishes, herrings, and others that do not live habitually on the coral reefs are not unlike in general colour and ornamentation the fish of temperate seas. Again, the crustacea and fish of the tropical rivers and lakes are not as a rule characterized by any peculiar colouring or marking. These peculiarities, then, are not directly due to the high temperature and bright light of the tropics, but they are due to the character of the surroundings.

Most of the colours must be considered to be concealment colours. *Stenopus hispidus*, though so very conspicuous when taken out of the water, was extremely difficult to see in the pool where I found it. I should, in all probability, have failed to notice it, had I not quite unintentionally and blindly touched it with my stick. Like all animals protected by concealment colours, it remained perfectly motionless when alarmed. When looking down on to the growing edge of a reef from a boat on a calm day, it is very difficult at first to see anything but the corals and sponges. After a time, when the eyes become more accustomed to the light, the fish may be distinguished. Those that are coloured blue are much less readily seen than the gold, yellow, and red varieties; but an examination of the fish that I caught myself, and were caught for me by the natives, showed that the fish in which blue is the prevailing colour are much more frequent in the very shallow water, while those that were caught in water from 15 to 20 fathoms were more frequently red or yellow. The blue colour seems to be a protection for the fish from air-breathing enemies—the eagles, ospreys, and hawks—and as these enemies can only approach them from above, the colours are frequently confined to the dorsal sides. The red and yellow colours of the fish seem to be a protection from animals, such as the sharks, perch, and other carnivorous fish, that approach them from the deeper waters beyond the reefs. Thus red and yellow fishes rarely have these colours confined to the upper sides, and many of the blue fishes are coloured red or yellow ventrally.

---

[1] Abstract of Lecture by Dr. S. J. Hickson, delivered at the London Institution, January 22, 1891.

It is difficult to frame any general rule to account for the curious distribution of the colours of these animals in spots and stripes. Speaking in very general terms, for there are many exceptions, the fish that browse on the corals, possessing small mouths and chisel-shaped teeth (such as the Chætodons, Trigger fish, and Surgeons), are striped; those that feed on other fish, and have large mouths armed with carnivorous teeth, such as the Serranidæ, are spotted.

The only example of what appears to be a warning colour that I have noticed occurs in connection with the spines on the tails of certain Surgeons and Trigger fish. *Acanthurus achillis*, for example, has a uniform purple colour, but there is a bright red patch surrounding the formidable tail spines that give these fish the name of Surgeons. Similar warning colours are very pronounced also in *Naseus unicornis* and *Naseus lituratus*, and in some of the Balistidæ.

WASHINGTON MAGNETIC OBSERVATIONS, 1886.[1]

THIS volume contains the results that have been obtained from the magnetic observations taken at the Naval Observatory during the years 1888 and 1889. The instruments with which they were made were, in the year 1887, placed in their respective buildings that had been erected for that purpose by the Bureau of Navigation. In the construction of these buildings the greatest care was taken to insure the complete elimination of local disturbances. No iron or any magnetic material was used at all, and the fastenings, &c., were entirely of copper, brass, and wood; even the stoves, in which only wood was burnt, were of soap-stone, with copper pipes.

The instruments that were employed consisted of a declinometer, theodolite, portable magnetometer, dip-circle, a set of self-recording magnetographs, a seismoscope, and seismograph; each of them, with the exception of the last two mentioned, being set on piers based on concrete, and in no way connected with the floors of the buildings. To complete the equipment, a compass-testing stand is placed on a pier north of the theodolite, and is capable of motion in an east and west direction. By means of an arm carrying two prisms that have adjusting screws, the opposite marks on the compass card can be placed in the field of view of the theodolite when the latter is directed on the prisms. All the observations, which are represented in tabular form, denote the results that have been obtained after applying all necessary corrections. The tables include, among others, the mean hourly values of the horizontal and vertical force for each month of 1889, and of the declination for each month of 1888 and 1889, the last of which are taken from the monthly curves; declination ordinates for each hour, in minutes of arc taken from daily declination traces; hourly values of horizontal and vertical force in absolute measure with all corrections; observations of horizontal intensity and dip, with a summary of disturbances in declination which differed two minutes or more from the mean monthly curve.

No less important is the series of the fourteen large plates at the end of the volume. The first shows the way that the daily photographic traces of declination, horizontal and vertical force are recorded; while the second illustrates the mean diurnal variation of the magnetic elements for the year 1889. In this latter plate the curve that gives the integration of these elements—that is, that gives the mean diurnal total force—brings out the fact that in every twenty-four hours there are two maxima and two minima, these latter two occurring between midnight and noon (75th meridian mean time).

Plates iii. to vi. inclusive show the traces of the monthly composite curves of declination for the two years.

In Plates vii. to xiv. most interesting comparison is made of the disturbed days of declination taken from observations at Washington, Los Angeles (California), Toronto (Canada), and Pawlowsk (Russia): the curves are all computed for the same time (*i.e.* for the 75th meridian west of Greenwich), and reduced to the same length of base line. Although on the whole the curves show a more or less equal variation, yet there are some cases in which a decided local variation has taken place. For instance, on January 20, between the hours of noon and four o'clock (75th meridian time), the magnetic declination at Washington, Los Angeles, and Toronto, shows only slight variations, while at Pawlowsk the disturbance is in comparison quite large. Another very interesting case happens on March 17, when the curves traced at Washington and Toronto are quite similar to each other, but different from those traced at the other two places: the curve showing the magnetic disturbances in declination at Pawlowsk being very similar to that indicating the horizontal force at Washington.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The subject of the Rede Lecture, to be given by Sir Alfred Lyall on June 17, is "Natural Religion in India."

The General Board of Studies have again brought forward proposals for the increase of the stipends paid to University Lecturers and Demonstrators in Natural Science, which had to be postponed last year owing to want of funds.

Mr. A. Hutchinson, Demonstrator of Chemistry in Caius College, has been recognized as a Teacher of Chemistry with reference to the regulations for medical degrees.

A Syndicate is proposed by the Council of the Senate for the purpose of considering whether any alternative for Greek should be permitted in the Previous Examination. This is sure to rouse much agitation, but it may be hoped that the long-vexed question will at length be settled in a liberal sense.

Another Syndicate is to consider the office of Superintendent of the Museums of Zoology and Comparative Anatomy, about to be vacated by Mr. J. W. Clark, Registrary. Some rearrangement of the duties, &c., is considered desirable.

SCIENTIFIC SERIALS.

American Journal of Science, May.—On the relationship of the Pleistocene to the pre-Pleistocene formations of the Mississippi basin, south of the limit of glaciation, by T. C. Chamberlain and R. D. Salisbury.—On certain measures of the intensity of solar radiation, by William Ferrel. The author shows that many measures of the intensity of solar radiation are of uncertain value. He specially discusses M. Crova's curves of the relative intensities of solar radiation, obtained at Montpellier with a modified form of the thermopile, called the registering actinometer.—Geological age of the Saganaga syenite, by Horace V. Winchell.—On a self-feeding Sprengel pump, by H. L. Wells.—Contributions to mineralogy, No. 50, by F. A. Genth; with crystallographic notes by S. L. Penfield and L. V. Pirsson. The composition and habits of the following minerals are given: three new varieties of axinite, eudialyte, and monticellite, and titanite from Magnet Cove, Arkansas.—

---

[1] Appendix I.—"Magnetic Observations." By Ensign J. A. Hoogewerff, U.S. Navy. (Washington: Government Printing Office, 1890.)

Contributions to mineralogy, No. 51, by F. A. Genth. A new species, which has been named aguilarite, is described. It appears to be a cupriferous stephanite with an admixture of metallic silver.—Columbite of the Black Hills, South Dakota, by W. P. Blake.—The raised reefs of Fernando de Noronha, by Henry N. Ridley.—The cause of active compressive stress in rocks and recent rock flexures, by T. Mellard Reade.—A new phosphate from the Black Hills of South Dakota, by W. P. Headden.—Note on certain peculiarities in the behaviour of a galvanometer when used with the thermopile, by Ernest Merritt.—Supplementary notice on the polycrase of North and South Carolina, by W. E. Hidden and J. B. Mackintosh.

THE *American Meteorological Journal* for March contains:—An article by S. M. Ballou, on Prof. Russell's theory of cold waves, published in the Report of the Chief Signal Officer for 1889. This article is a reprint of a paper read at the meeting of the New England Meteorological Society on January 20 last. According to Prof. Russell's theory, the cause of the cold area from which the cold wave is drawn is held to be a preliminary strong upward diminution of temperature in the air, a subsequent overturning, bringing the cold air to the surface and producing uniform temperature upwards, and a further cooling above, producing high pressure. The author points out that each of these assumptions would probably be questioned, and he considers each of them in detail, quoting from the works of various authorities upon the subject.—Temperature in high and low areas. This is a translation of the substance of a reply by Dr. Hann, in the *Meteorologische Zeitschrift* of September 1890, to the criticisms of Prof. Hazen. These papers have already been noticed at length in NATURE.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, April 30.—"The Passive State of Iron and Steel, Part III." By Thos. Andrews, F.R.S., M.Inst.C.E.

Series V., Set 1. *Relative Passivity of Wrought-iron and various Steel Bars, and the Influence of Chemical Composition and Physical Structure on their Passive State in Cold Nitric Acid.*—The passive state of iron or steel may have hitherto been regarded by many as a sort of fixed property pertaining to iron and steel alike, when immersed in cold strong nitric acid. The following experiments were made to investigate if the passivity was of a universally static character, or whether it varied with the chemical composition and general physical structure of the metal, and, if so, to what extent.

The experiments of Series V., Set 1, were made on bars of the various steels selected from the author's standard samples. The bars were cold drawn through a wortle, and were therefore different in physical structure to the rolled plates used in the second series of the experiments. An idea of their general properties will be obtained on reference to Part II., Tables IV. and V. A polished bar, 8¼ inches long, 0·310 inch diameter, of the steel to be tested was placed in the wooden stand W, along with a polished wrought-iron bar of equal size, and the pair were then immersed in 1¼ fluid ounce of nitric acid, 1·42 sp. gr., contained in the U-tube, the bars being in circuit with the galvanometer. The immersion was continued for the periods stated, and with the electro-chemical results given on Table VI.

The wrought-iron bars used in each experiment were cut from one longer polished rod, so as to afford a fair comparison of the relative passivity of the various steels, compared with the wrought-iron and also with each other. The results are the average of numerous experiments in each case.

The experiments of Series V., Set 1, on the relative passivity of wrought-iron, soft cast-steel, hard cast-steel, soft Bessemer steel, and tungsten steel, showed that wrought-iron was electro-positive to the steels with a considerable E.M.F., the wrought-iron being thus shown to be less passive than the steels.

Series V., Set 2. *Relative Passivity of Wrought-iron and various Steel Plates in Cold Nitric Acid*, sp. gr. 1·42.—In the following series of observations, the metals experimented upon consisted of plates of rolled wrought-iron, rolled steels made by the Bessemer, Siemens-Martin, or crucible cast steel processes, such as soft cast-steel, hard cast-steel, soft Bessemer steel, hard Bessemer steel, soft Siemens steel, hard Siemens steel, and they are of the chemical composition given on Table VII. The terms "soft" and "hard" relate only to difference of percentage of combined carbon, and not to their having undergone annealing or hardening processes. Each plate was 3 inches square, by ⅛ inch thick = total area of exposure 19·5 square inches including edges, brightly polished all over, and had a long thin strip left on the top side, for convenience of attaching to the galvanometer connections. The whole of the wrought-iron plates, used as elements with the various steel plates, were cut from one larger wrought-iron plate, and were thus practically of uniform composition, thus ensuring an accurate comparison of the relative passivity of the wrought-iron compared with the different types of steels, and at the same time indicating relatively the influence of varied composition and structure on the passivity of the different classes of steels under observation. In each experiment, a polished wrought-iron plate and a polished steel plate were firmly placed in two small holes drilled through a thick plate-glass cover; the cover holding the two plates was then carefully placed closely over a porcelain vessel containing 15 fluid ounces of nitric acid, sp. gr. 1·42, the plates being fully immersed in the acid, and the protruding shanks of the bars connected in circuit with the galvanometer. The electro-chemical effects observed were then taken in the usual manner, and the results are given in detail on Table VIII., and indicated that wrought-iron was less passive than the steels, and further demonstrated that steels of a higher percentage of combined carbon are more passive than those of a lower percentage of combined carbon.

General Remarks.—It has been necessary to give in modified detail the effects observed during the periods of experimentation recorded on the Tables, Parts I., II., and III., so as to convey an accurate intimation of the method and nature of the research; and a brief *résumé* of some of the principal results and conclusions arrived at by the author up to the present time may now be given.

(1) The experimental observations of Part I., Series I., indicate that the influence of magnetization on the passive state of steel rods in cold nitric acid, sp. gr. 1·42, is not very great, but it was detectable with the delicate galvanometer and by the sensitive electro-chemical method pursued by the author in the investigation.

The effect of magnetization is more marked in warm nitric acid and when the iron is in a powdered state, as shown in the independent and separate experiments of Messrs. Nichols and Franklin on passive powdered iron in warm nitric acid, previously alluded to in Part I., by whom it was shown that the temperature of transition from the passive to the active state was very materially lowered by powerful magnetism; their experiments also indicate that the passive state of powdered iron cannot be fully overcome, even under strong magnetic influence, until a temperature of about 51° C. is reached.

(2) The author's experiments of Part I., Series II., at higher temperatures, confirm those of Part I., Series I., and further tend to demonstrate the influence of magnetization in somewhat lessening the passivity of steel, showing that even previous to the critical temperature point of transition from the passive to the active state, magnetized steel bars were rather less passive in warm nitric acid than unmagnetized ones.

(3) The results in Part II., Series III., show that the passivity of both unmagnetized wrought-iron and unmagnetized steel in nitric acid, sp. gr. 1·42, is considerably and proportionately reduced as the temperature of the acid increases, until the temperature point of transition from the passive to the active state is reached at a temperature of about 195° F., and it was also found that the wrought-iron was less passive in the warm nitric acid than cast-steel. (See also remarks at foot of Diagram I. in Part II.)

(4) The results of the observations of Part II., Series IV., indicate that Scheurer-Kestner was, to some extent, in error in regarding the passivity of iron as not dependent on the greater or less degree of saturation of the acid. The author's experiments herein recorded have shown that the passivity of the metals employed, viz. wrought-iron, soft cast-steel, hard cast-steel, soft Bessemer steel, and tungsten steel, was very materially increased with the concentration of the nitric acid; and it was also observed that wrought-iron was much less passive in the nitric acid of less concentration than most of the steels, the soft Bessemer steel being found about equal in passivity to the wrought-iron under the conditions of experimentation. A re-

ference to Table III. shows that a considerable amount of E.M.F. was developed between the various metals in every instance, which is a circumstance of much interest in connection with the passive state of iron and steel.

(5) The results obtained in Part III., Series V. and VI., on the relative passivity of wrought-iron and the various steels—soft cast-steel, hard cast-steel, soft Bessemer steel, hard Bessemer steel, soft Siemens steel, and hard Siemens steel—are of an important character, showing, by the delicate electro-chemical method employed, the sensitive influence of difference in chemical composition and physical structure, &c., on the passive state of the metals. Generally throughout this series of experiments it will be observed that the wrought-iron was electro-positive to the steels with a considerable E.M.F., amounting, in some cases, to as high as one-tenth to one-seventh of a volt, the wrought-iron being thus shown to be less passive than the steels.

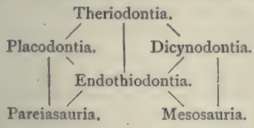
A reference to the experiments on the wrought-iron and various steel plates, on Table VIII., shows that the E.M.F. between the passive wrought-iron and the various soft steels, which contained less percentage of combined carbon, in circuit in cold nitric acid, sp. gr. 1·42, was very considerably less than the E.M.F. under similar conditions between the wrought-iron plates and the different hard steels having a higher percentage of combined carbon. The latter results, therefore, demonstrate the interesting circumstance that steels of a higher percentage of combined carbon are more passive than those of a lower percentage of combined carbon. It will be observed that the wrought-iron was also electro-positive to most of the steels, whether of a higher or lower percentage of combined carbon, which shows that wrought-iron may be regarded as generally less passive than steels.

May 14.—"Researches on the Structure, Organization, and Classification of the Fossil Reptilia. VII. Further Observations on *Pareiasaurus*." By H. G. Seeley, F.R.S., Professor of Geography in King's College, London.

All the affinities hitherto attributed to *Pareiasaurus* with Labyrinthodonts, Anomodonts, *Procolophon*, and Mammals are shown more strongly in the several parts of the skeleton, by the new evidence. The shoulder-girdle is more Labyrinthodont than was previously supposed, the skull is more Reptilian, and the pelvis and limbs are more Mammalian, though with some resemblance to Dinosaurs.

From furthur evidence of the structure of the skeleton in *Procolophon*, the author regards that type as a member of the Pareiasauria, rather than as forming a distinct sub-order. It also has four sacral vertebræ.

The divisions of the Anomodontia are grouped as—



Physical Society, May 9.—The Society varied its ordinary procedure by paying a visit to the ancient seat of learning situated on the banks of the Cam. Assembling at Liverpool Street Station, members and visitors to the number of about one hundred were conveyed in saloon carriages by the 11 o'clock express direct to their destination, the whole journey being accomplished in about seventy-five minutes. Amongst those present were Dr. E. Atkinson, Prof. Ayrton and Mrs. Ayrton, Mr. Walter Baily, Mr. Shelford Bidwell and Mrs. Bidwell, Mr. D. J. Blaikley, Mr. T. H. Blakesley and Mrs. Blakesley, Mr. J. T. Bottomley, Mr. C. V. Boys, Prof. Carey Foster, Mr. Conrad W. Cooke, Prof. Fitzgerald, Dr. E. Frankland and Mrs. Frankland, Dr. W. R. Hodgkinson, Prof. O. J. Lodge, Prof. Meldola, Prof. Perry and Mrs. Perry, Prof. Rücker, Dr. Sumpner, Prof. S. P. Thompson and Mrs. Thompson, Mr. A. P. Trotter and Mrs. Trotter, and Mr. G. M. Whipple. On arriving at the historic town the party became the guests of the Cambridge members, and proceeded to Emmanuel College, where they were received by Mr. W. N. Shaw. Various groups visited the cloisters, chapel, and gardens, and at one o'clock lunch was provided in the College Hall. At 2.30, a meeting of the Society was held in the Lecture Room of the Cavendish Laboratory. The papers read were all by authors resident in Cambridge, and the abstracts given below will sufficiently indicate the variety of the subjects brought before the Society. After the meeting the visitors inspected the Cavendish Laboratory. Amongst the many interesting instruments and apparatus to be seen, specially noticeable were Prof. J. J. Thomson's 50-feet vacuum tube, glowing from end to end with a luminous discharge; Mr. Shaw's pneumatic bridge, by which the pneumatic resistance or conductivity of various shaped orifices and channels can be compared; and the new air condensers to be used by Mr. Glazebrook as standards. The Cambridge Scientific Instrument Company had an interesting exhibit, including a dividing engine, Boys's radio-micrometer, electrically driven tuning-forks, and various recording instruments, amongst which was Galton's apparatus for registering the growth of plants. Other things which attracted attention were Glazebrook's spectrophotometer; Lord Rayleigh's coils and apparatus used in his determination of the ohm; a collection of models, medals, and instruments, formerly belonging to Prof. Maxwell; the resistance standards of the British Association, together with the historic rotating coils and electrodynamometer used in the determination of the B.A. unit. Tea was served in the Combination Room of Trinity College, and a majority of the visitors returned to town by the 8 o'clock express, greatly pleased with the day's outing. Others, however, prolonged their visit until Monday, and had opportunities of discussing important physical problems with the Cambridge members. The meeting was in every sense a great success, and will long be remembered as a red-letter day in the history of the Society.—At the science meeting, held in the Cavendish Laboratory, Prof. Ayrton, F.R.S., President, in the chair, the following communications were made:—Some experiments on the electric discharge in vacuum tubes, by Prof. J. J. Thomson, F.R.S. The phenomena of vacuum discharges were, he said, greatly simplified when their path was wholly gaseous, the complication of the dark space surrounding the negative electrode and the stratifications so commonly observed in ordinary vacuum tubes being absent. To produce discharges in tubes devoid of electrodes was, however, not easy to accomplish, for the only available means of producing an electromotive force in the discharge circuit was by electro-magnetic induction. Ordinary methods of producing variable induction were valueless, and recourse was had to the oscillatory discharge of a Leyden jar, which combines the two essentials of a current whose maximum value is enormous, and whose rapidity of alternation is immensely great. The discharge circuits, which may take the shape of bulbs or of tubes bent in the form of coils, were placed in close proximity to glass tubes filled with mercury, which formed the path of the oscillatory discharge. The parts thus corresponded to the windings of an induction coil, the vacuum tubes being the secondary and the tubes filled with mercury the primary. In such an apparatus the Leyden jar need not be large, and neither primary or secondary need have many turns, for this would increase the self-induction of the former and lengthen the discharge path in the latter. Increasing the self-induction of the primary reduces the E.M.F. induced in the secondary, whilst lengthening the secondary does not increase the E.M.F. per unit length. Two or three turns in each were found to be quite sufficient, and on discharging the Leyden jar between two highly polished knobs in the primary circuit a plain uniform band of light was seen to pass round the secondary. An exhausted bulb containing traces of oxygen was placed within a primary spiral of three turns, and on passing the jar discharge a circle of light was seen within the bulb in close proximity to the primary circuit, accompanied by a purplish glow which lasted for a second or more. On heating the bulb, the duration of the glow was greatly diminished, and it could be instantly extinguished by the presence of an electro-magnet. Another exhausted bulb surrounded by a primary spiral was contained in a bell jar, and when the pressure of air in the jar was about that of the atmosphere, the secondary discharge occurred in the bulb, as is ordinarily the case. On exhausting the jar, however, the luminous discharge grew fainter, and a point was reached at which no secondary discharge was visible. Further exhaustion of the jar caused the secondary discharge to appear outside the bulb. The fact of obtaining no luminous discharge either in the bulb or jar the author could only explain on two suppositions, viz. that under the conditions then existing the specific inductive capacity of the gas was very great, or that a discharge could pass without being luminous. The author had also observed that the conductivity of a vacuum tube without electrodes increased as the pressure diminished, until a certain point was reached, and afterwards diminished again, thus showing that the high resistance of a nearly perfect vacuum is in no way due to the presence of the electrodes. One peculiarity of the discharges was their local nature, the rings of light being much more sharply defined than was to be expected. They were also found to be most easily produced when the chain of molecules in the discharge were all of the same kind. For example, a discharge could be easily sent through a tube many feet long, but the introduction of a small pellet of mercury in the tube stopped the discharge, although the conductivity of the mercury was much greater than that of the vacuum. In some cases he had noticed that a very fine wire placed within a tube on the side remote from the primary circuit would present a luminous discharge in that tube.—Some experiments on the velocities of the ions, by Mr. W. C. D. Whetham. In studying electrolysis the question as to whether there is any transference of solvent when a porous wall is absent presented itself to the author. The ordinary methods of testing for transference, such as by increase of pressure, or by overflow, not being available, when there is no diaphragm, the author used different coloured solutions of the same salt, such as cobalt chloride in water and in alcohol, the former of which is red and the latter blue. By putting the solutions into a kind of **U**-shaped tube any change in the position of the line of junction of the two liquids could be measured. Two aqueous solutions in which the anion was the same were also tried, one combination being cupric chloride and common salt, and in this case the line of demarcation traversed about 7 inches in three hours. The results hitherto obtained by this method agreed fairly with those found by Kohlrausch.—On the resistance of some mercury standards, by Mr. R. T. Glazebrook, F.R.S. In 1885, M. Benoit, of Paris, supplied the author with three mercury standards, nominally representing the Paris Congress ohm, now commonly known as the legal ohm. Tests of these standards were described in a paper read before the Physical Society in 1885 by the present author. Recently he had occasion to compare two of the standards with the British Association coils. The mean of many concordant results gave the resistance of one of the mercury standards (No. 37) as 1·01106 B.A.U., whilst that of the other (No. 39) was 1·01032 B.A.U. Expressing them in legal ohms the present resistances are (No. 37) 0·99986 and (No. 39) 0·99913, whilst in 1885 the values obtained were (No. 37) 0·99990 and (No. 39) 0·99917. This shows that within the limits of experimental error the ratios of the mercury standards to the B.A. coils have remained practically unchanged during six years. The numbers given above are based on Lord Rayleigh's determination of the specific resistance of mercury, which differs appreciably from that found by Mascart and other observers. Taking the mean of the later concordant determinations, the values of the mercury standards expressed in legal ohms become (No. 37) 1·00033 and (No. 39) 0·99959. The values given by the maker were 1·00045 and 0·99954 respectively, showing a very close agreement. The author also found that refilling No. 37 from the same sample of mercury produced no appreciable change in its resistance, whilst No. 39 was somewhat affected by a similar operation. Experiments on the co-efficient of increase of resistance of mercury with temperature gave the value 0·000872 as the mean coefficient between 0° and 10° C., a number rather less than that obtained by Kohlrausch.—On an apparatus for measuring the compressibility of liquids, by Mr. S. Skinner. The apparatus consisted of a large spherical flask, with a long narrow neck containing the liquid to be experimented upon, the lower part of which was in communication through a stopcock and flexible tube with an adjustable reservoir. By raising or lowering the latter the flask could be easily filled or emptied or the quantity of liquid adjusted. The flask was inclosed in a bell jar, whose interior was in communication with a pump and barometer gauge. So sensitive was the arrangement that the compression of water produced by blowing into the jar caused the liquid to descend about 1 centimetre in the neck of the flask. This movement corresponded with a change of volume of about half a millionth. The coefficient of compressibility had been tested at different temperatures, and the results were not very different from those obtained by Tait and others. The influence of salts in solution in changing the compressibility had also been tested, and a great difference in this respect found between electrolytes and non-electrolytes.—Some measurements with the pneumatic bridge, by Mr. W. N. Shaw. The action of the apparatus is analogous in many respects to the Wheatstone's bridge, and its object is to compare the pneumatic resistances or conductivities of various orifices, channels, tubes, &c. The proportional arms are represented by two circular holes in thin plates of mica, the third arm by an aperture provided with a sliding shutter adjustable by a screw, and the fourth might consist of any aperture or tube whose conductivity was to be determined. The several apertures are pneumatically connected by large wooden boxes. The battery takes the form of a Bunsen burner with a long chimney, whilst the galvanometer is represented by a glass tube connecting opposite chambers, and containing a vane which sets itself at right angles to the tube when no air current is passing. The apparatus is remarkably sensitive to movements of the shutter, and on starting or stopping the draught after balance had been obtained, effects analogous to those produced by self-induction are observed. By its use it has been found that bevelling off one side of a hole in a thin plate increases the pneumatic conductivity of the aperture very considerably, particularly when the bevel is on the egress side. Another interesting result is that for square-ended tubes of given size the conductivity first increases as the length is made greater, and afterwards diminishes with further increase of length. Putting a flange on the outlet end reduces the anomalous effect, whilst a bevelled mouthpiece similarly placed causes it to disappear. In the discussion on Prof. Thomson's paper, Prof. Fitzgerald said the beautiful experiments were likely to lead to very important results. He did not quite understand how placing a fine wire in a vacuum tube could prevent the luminous discharge, for if the wire was on the side remote from the primary, and if there was any great increase in specific inductive capacity, he would have expected the air to screen the wire. Prof. Lodge asked for further information as to the action of the magnet in preventing the after-glow, and in some cases precipitating a luminous discharge. The experiment with the exhausted bulb within the bell jar was also difficult to understand, and he did not see why one of Prof. Thomson's two suppositions must necessarily be true. The President inquired whether Prof. Thomson had tried Mr. Crookes's experiment, in which the electric pressure necessary to produce a discharge was greatly lessened by putting a phosphorescent material in the tube. Prof. Thomson, in reply, said he had not tried the experiment, but the phosphorescence he had observed was of quite a different character from that produced in Mr. Crookes's tubes. To Prof. Fitzgerald he said the action of the wire was probably a question of time, and thought the whole field was in some way thrown on the wire and thus discharged. In reply to Prof. Lodge, he had not ascertained the true nature of the effect of a magnet on the glow, but he believed the glow to be due to a combination which might be prevented or facilitated by the action of the magnet causing the density to be different in different parts of the bulb. M. Guillaume, in discussing Mr. Skinner's paper, described the methods used by Sabine, Jamin, and others, in determining the compressibility of liquids, and pointed out their defects. The chief difficulty in such experiments was in finding the compressibility of the reservoir. Numbers expressing the compressibility of mercury obtained by different observers were given, the best values varying between 0·0000039 and 0·0000040.—On the motion of Prof. Ayrton, seconded by Prof. Rücker, a hearty vote of thanks was accorded to the authors for their valuable and interesting communications, and for the kind manner in which the Society had been received and entertained by the Cambridge members. Prof. Thomson and Mr. Glazebrook acknowledged the vote.

Geological Society, May 6.—Dr. A. Geikie, F.R.S., President, in the chair.—The following communications were read:—On a Rhætic section at Pylle Hill or Totter Down Bristol, by E. Wilson. In a deep railway-cutting at Pylle Hill, the Rhætic beds, having a thickness of not more than seventeen feet, are exposed between the Tea-Green Marls and the Lower Lias. There is no doubt as to the division between the Rhætic and Keuper beds in this section, but the line of demarcation between the Rhætic and the Lias has always been a matter of uncertainty in the West of England. In connection with this subject the term "White Lias," as applied to beds some of which are Rhætic and others Liassic, is held to be unsatisfactory. The author takes a limestone which is the equivalent of the Cotham Marble as the highest Rhætic bed in the section described. He divides the Rhætic beds of the cutting into an Upper Rhætic series and *Avicula contorta* Shales. The intimate connection betwixt the Tea-Green Marls and the Red Marls of the Upper Keuper is well displayed, whilst there is a sharp line of demarcation between the former and the *Avicula contorta* Shales. Most of the characteristic fossils of the British Rhætic are met with at Pylle Hill, together with a few forms which are new to England, and some of these possibly to science. A detailed section of the subdivisions of the Rhætic and adjacent beds, and a list of Rhætic fossils found in the section are given by the author. After the reading of the paper some remarks were made by Mr. Etheridge, Mr. H. B. Woodward, the Rev. H. Winwood, and Prof. T. Rupert Jones.—A microscopic study of the Inferior Oolite of the Cotteswold Hills, including the residues insoluble in hydrochloric acid, by Edward Wethered. The author gives the following main divisions of the Inferior Oolite of the Cotteswold Hills in descending order :—

Ragstones.
Upper Freestones.
Oolitic Marl.
Lower Freestones.
Pea Grit.
Transition Beds resting on Upper Lias.

The strata are described, and the results of microscopic examination of the different beds given. These latter confirm the author's views as to the important part which *Girvanella* have taken in the formation of oolitic granules ; whilst an examination of the borings referred to by Prof. Judd in the discussion of Mr. Strahan's paper "On a Phosphatic Chalk," convinces the author that these have no connection with the genus *Girvanella*. In the second part of the paper the insoluble residues left after treating the various deposits with acid are considered. They contain chiefly detrital quartz, felspars, zircons, tourmaline, chips of garnet, and occasionally rutile. In the argillaceous beds silicate of aluminia was found to occur plentifully. The detrital material is considered to be due to denudation of crystalline felspathic rocks, and not of stratified ones. This view seems to be supported by the quantity of felspar and its good state of preservation. The paper concludes with a consideration of the quantity of residue and the size of the quartz-grains in the different deposits, which are summarized in the following table :—

	Percentage of residue.	Size of quartz-grains, in millim.
Ragstones	2·8 ...	·17
Upper Freestones ...	1·1 ...	·12
Oolitic Marl	3·2 ...	·09
Lower Freestones ...	1·8 ...	·13
Pea Grit Series	5·0 ...	·14
Transition Beds	38·3 ...	·13

This shows a great falling off in the percentage of residue above the Transition Beds. That of the Freestones is remarkably low, and it would appear that these rocks were formed under conditions which allowed of very little sediment being deposited. The paper gave rise to a discussion, in which Prof. Hull, Mr. Etheridge, Mr. H. B. Woodward, the Rev. H. Winwood, and the author took part.

Royal Meteorological Society, May 20.—Mr. Baldwin Latham, President, in the chair.—The following papers were read :—On the vertical circulation of the atmosphere in relation to the formation of storms, by Mr. W. H. Dines. After giving an outline of the circulation of the atmosphere, the author refers to the two theories which have been suggested to account for the formation of storms, viz. (1) the convection theory, which is that the central air rises in consequence of its greater relative warmth, this warmth being produced by the latent heat set free by condensation ; and (2) the theory that the storms are circular eddies produced by the general motion of the atmosphere as a whole, just as small water eddies are formed in a flowing stream of water. The author is of opinion that the convection theory is the more probable of the two, but more information about the temperature of the upper air is greatly needed.—On Brocken spectres in a London fog, by Mr. A. W. Clayden. During the dense fogs in February last, the author made a number of experiments with the view of raising his own spectre. This he ultimately succeeded in accomplishing by placing a steady limelight a few feet behind his head, when his shadow was projected on the fog. He then made some careful measurements of the size and distance of the spectre, and also succeeded in taking some photographs of the phenomenon.—An account of the "Leste," or hot wind of Madeira, by Dr. H. Coupland Taylor. The "Leste" is a very dry and parching wind, sometimes very hot, blowing over the island from the E.N.E. or E.S.E., and corresponds to the sirocco of Algeria, or the hot north winds from the deserts of the interior experienced in Southern Australia. During its prevalence a thin haze extends over the land, and gradually thickens out at sea until the horizon is completely hidden. It is most frequent during the months of July, August, and September, and usually lasts for about three days.—Mr. Shelford Bidwell, F.R.S., exhibited an experiment showing the effect of an electrical discharge upon the condensation of steam. The shadow of a small jet of steam cast upon a white wall is, under ordinary conditions, of feeble intensity and of a neutral tint. But if the steam is electrified, the density of the shadow is at once greatly increased, and it assumes a peculiar orange-brown hue. The electrical discharge appears to promote coalescence of the exceedingly minute particles of water contained in the jet, thus forming drops large enough to obstruct the more refrangible rays of light. It is suggested that this experiment may help to explain the intense darkness, often tempered by a lurid yellow glow, which is characteristic of thunderclouds.

Linnean Society, April 16.—Prof. Stewart, President, in the chair.—A paper by the Rev. F. R. Wilson, was read, on lichens from Victoria, in which several new species were described, specimens of which were exhibited.—A paper by Surgeon-Major A. Barclay followed, on the life-history of two species of *Puccinia*, viz. *P. coronata*, Corda, and a new species which the author proposed to name *P. Jasmini-chrysopogonis*. A feature of peculiar interest noted in the latter species was the extraordinary abundance and wide distribution of the teleutosporic stage as compared with the comparative scarcity of the æcidial stage, and this disproportion in the distribution of the two stages had been remarked by the author long before he had ascertained that they were related.—A discussion followed, in which several of the botanists present took part.

May 7.—Prof. Stewart, President, in the chair.—Prof. R. J. Anderson exhibited a panoramic arrangement for displaying drawings at biological lectures.—Mr. John Young exhibited a nest of the Bearded Titmouse (*Calamophilus biarmicus*), which had been built in his aviary. Several eggs were laid, but none of them were hatched.—The Rev. E. S. Marshall exhibited several specimens of a Cochlearia from Ben More, believed to be undescribed.—Mr. Robert Deane forwarded for exhibition a plant of the Rayless Daisy, found growing abundantly in the neighbourhood of Cardiff ; and an undetermined Sponge, dredged in about 40 fathoms, off the coast of South Wales.—Mr. D. Morris drew attention to a Jamaica drift fruit recently found on the coast of Devonshire. Although figured so long ago as 1640 by Clusius, and subsequently noticed by other observers, the plant yielding it had only lately been identified by Mr. J. H. Hart, of Trinidad, as *Sacoglottis amazonica*. Mr. Morris likewise exhibited specimens of the fruit of *Catostemma fragrans*, received for the first time, from St. Vincent, showing its true position to be amongst the *Malvaceæ*, tribe *Bombaceæ*.—Mr. Thomas Christy exhibited some Kola nuts, and made remarks on the properties attributed to their medicinal use.—A paper was then read by Mr. Malcolm Lawrie, on the anatomy of the genera *Pterygotus* and *Slimonia*, and their relationship to recent *Arachnida*. An interesting discussion followed, in which the President, Prof. Howes, Dr. H. Woodward, and others took part.

Entomological Society, May 6.—Mr. Frederick DuCane Godman, F.R.S., President, in the chair.—Dr. D. Sharp exhibited a number of eggs of *Dytiscus marginalis* laid on the sheath of a species of reed, and commented on the manner of their oviposition, which he said had been fully described by Dr. Régimbart.—The Rev. A. E. Eaton exhibited a collection of *Psychodidæ* from Somersetshire, including six species of *Psychoda*, eleven species of *Pericoma*, and one species of *Ulomyia*. Mr. McLachlan commented on the interesting nature of the exhibition.—Mr. P. Crowley exhibited a specimen of *Prothoë caledonia*, a very handsome butterfly from Perak ; and a specimen of another equally handsome species of the same genus from Tonghou, Burmah, which was said to be undescribed.—Mr. H. Goss, the Secretary, read a letter from Mr. Merrifield, pointing out that the statement made by Mr. Fenn, at the meeting of the Society on April 1 last, of his views on the effects of temperature in causing variation in Lepidoptera, was incorrect ; he (Mr. Merrifield) had never suggested what might happen to *Tæniocampa instabilis*, and had expressly stated that he had found a reduction of the temperature below 57° to produce no effect, whereas in Mr. Fenn's experiments the temperature must have been below 40°.—The Secretary also read a letter which Lord Walsingham had received from Sir Arthur Blackwood, the Secretary of the Post Office, in answer to the memorial which, on behalf of the Society, had been submitted to the Postmaster-General, asking that small parcels containing scientific specimens might be sent to places abroad at the reduced rates of postage applicable to packets of *bonâ fide* trade patterns and samples. The letter intimated that, so far as the English Post Office was concerned, scientific specimens sent by sample post to places abroad would not be stopped in future.

Mathematical Society, May 14.—Prof. Greenhill, F.R.S., President, in the chair.—The following communications were made:—Relations between the divisors of the first n numbers, by Dr. Glaisher, F.R.S.—Wave motion in a heterogeneous heavy liquid, by Mr. Love.—Disturbance produced by an element of a plane wave of sound or light, by Mr. Basset, F.R.S.—On functions determined from their discontinuities and a certain form of boundary condition, and on a certain Riemann's surface, by Prof. W. Burnside.—Messrs. MacMahon, Larmor, Bryan, and the President took part in the discussions on the papers.

CAMBRIDGE.

Philosophical Society, May 4.—Prof. G. H. Darwin, President, in the chair.—The following communications were made:—The most general type of electrical waves in dielectric media that is consistent with ascertained laws, by Mr. J. Larmor.—A mechanical representation of a vibrating electrical system and its radiation, by Mr. J. Larmor.—The theory of discontinuous fluid motion in two dimensions, by Mr. A. E. H. Love. The paper contains an account of a modification of Mr. Michell's method. It is shown that, in all problems where the fixed boundaries consist of parts of *straight* lines, a figure can be constructed whose conformable representation upon a half plane gives rise to the equation of transformation which contains in itself the solution of the problem. The relation by which the representation is effected can in each problem be determined by known methods. The whole subject is thus reduced to integral calculus. Several new cases of the resistance offered by obstacles to the motion of fluids are solved. These include the determination of the mean pressure on a disk with an elevated rim, and of the mean pressure on a pier or other obstruction in a canal of finite breadth.—On thin rotating isotropic disks, by Mr. C. Chree. The subject treated is that of the rotation about their axes of thin disks whose section parallel to the plane faces consists of a circle or the area between two concentric circles. The paper aims at providing a solution which is not open to the objections recently urged by Prof. Pearson in NATURE against previous solutions.

PARIS.

Academy of Sciences, May 19.—M. Duchartre in the chair.—Determination of the constant of aberration; numerical values deduced from two groups of four stars, by MM. Lœwy and Puiseux.—On the transit of Mercury, by M. J. Janssen. It is remarked that a conclusive confirmation of the solar origin of the corona would be obtained if Mercury were photographed when at a short distance from the edge of the sun, and appeared in the negative projected upon a luminous background.—On the physical explanation of fluidity, by M. Boussinesq.—The heat of combustion and formation of some chlorine compounds, by MM. Berthelot and Matignon. The experiments indicate that for each equivalent of hydrogen replaced by chlorine in a series of compounds from 30 to 32 calories is disengaged. Cl_n substituted for H_n thus disengages about $30n$ calories.—On a double halo with parhelia observed on May 15, 1891, by M. A. Cornu.—On a memoir, by Herr W. von Bezold, relative to the theory of cyclones, by M. Faye.—Remarks on the employment of carbon bisulphide in the treatment of phylloxerous vines, by M. A. F. THE BRITISH INSTITUTE OF PREVENTIVE MEDICINE.

THE progress of bacteriological science, and the amount of exact information which it has shed upon the problems of disease during the last fifteen years, have led several of the Governments of the Continent and America to establish institutes providing for original research, as well as technical instruction, in preventive medicine.

This country, on the other hand, which pioneered sanitary science from its birth, has, strangely enough, been distinctly behindhand in the study of bacteriology (fraught as it is with interest of such vital importance to the health and prosperity of the nation); and of the provision of institutes of the kind which have been established abroad, such as the Pasteur Institute in Paris, the Hygienische Institut in Berlin, Königsberg, Breslau, Wiesbaden, St. Petersburg, Moscow, Odessa, Tiflis, Warsaw, Cracow, Naples, Turin, Rome, Milan, Palermo, Malta, Barcelona, Constantinople, Bucharest, Budapest, Rio Janeiro, New York, Washington, we have no example in the United Kingdom. In these institutions, the study of the morphology, biology, physiology, and chemistry of micro-organisms, whether pathogenic or not, is being actively pushed forward, and a thorough analysis of their subtle influence as causative factors of disease pursued.

In this manner the poisons of the following maladies, the effects of which are among the direst evils to humanity, viz. pyæmia, anthrax, erysipelas, septicæmia, glanders, tubercle, diphtheria, &c., have been isolated, and discovered to be micro-organisms which are now known certainly to be the active principle of the virus. When we reflect that, for centuries and centuries, the crippling effects of epidemic and devastating diseases have been only too well known, but attributed to the operation of all manner of causes, *e.g.* supernatural agencies, Divine wrath, meteorological and climatic influences, &c., &c., the fact that the real truth concerning the nature of their causes has been ascertained only within the last few years by laboratory research is, in itself, overwhelmingly expressive of the immense value of Bacteriological Institutes and their work.

But their value does not stop here. Knowing, as thanks to bacteriology we now do, the origin of these diseases, it may be asked what has the same science done towards stamping them out and preventing their development, or haply arresting their progress should they unfortunately gain access to, and invade, the tissues of the body. To express ourselves more plainly, the question might be put in this form, "What has bacteriological science done to discover the antidotes of such poisons?" The answer is, that whereas centuries of clinical observation have done very little indeed—by watching the sick and the employment of drugs—towards the direct arrest of the virus of infective maladies, laboratory work, on the other hand, has already provided us, not merely with many invaluable and additional facts to general science on the subject of immunity, vaccination, *i.e.* protection before infection, resistance of tissues to invasion by parasitic organisms, &c.; but has given to medical science, what no pharmacopœia has ever been able to do—namely, chemical antidotes which by their specific action upon the virus of diseases alone successfully save human beings as well as the lower animals from death and incapacitating illness.

Of these new methods, perhaps the most noteworthy is Pasteur's treatment of hydrophobia, but others have been already discovered, and are being examined and tested for practical employment in medicine and surgery.

A large institute of this kind, however, is not reserved solely for the investigation of the problems of disease—on the contrary, it has a far wider sphere of usefulness. Bacteriology, which Pasteur showed was the key to the secrets of fermentation, is, of necessity, all-important to many very extensive trades and commercial undertakings. The botanical and biological researches of the Pasteur Institute are thus to a large extent utilized by the French manufacturers, as well as by those of other countries, to their great profit.

The particular bearing of this branch of science has never been fully comprehended by the public, who are not aware what an enormous debt of obligation they owe to M. Pasteur, and to the extension of scientific research, which received its impetus from his genius, and which has resulted in so much direct gain and benefit to the community. In like manner, to agriculture, the questions of changes in soils—such, for example, as nitrification, now known to be due to the action of micro-organisms—are not less important, and indeed essential. A Bacteriological Institute, therefore, has in agriculture, quite apart from the subject of diseases of animals, a fertile source of work of the utmost value and assistance to practical men. But, in addition, there has of later years arisen a branch of chemical industry directed towards the synthetic production of numerous substances which prove to be powerful drugs. The knowledge of these is, of course, incomplete and dangerous until thorough experimental investigation of the action of these substances has been made. In this country, however, our chemists are precluded, by the harassing legislation under which their co-workers in physiology, pathology, and medicine labour, from pursuing this useful line of research, without great trouble and endless restrictions, although such work is solely directed towards the therapeutic relief of disease and suffering.

The chemistry of disinfection offers in itself an extensive field of research which can alone be cultivated in an institution of this kind reserved for bacteriological investigations.

Lastly, in such an institute two subjects of general interest receive special careful attention. These are (1) the technical instruction of medical men, health officers, chemists, and manufacturers, in bacteriology, both in its morphological and biological aspects; and (2) the examination of tissues and substances suspected to be the seat or vehicle of infectious diseases and submitted for investigation and report. The functions of a Bacteriological Institute, therefore, clearly involve interests of the highest national as well as particular or individual import.

Since the formation of the Pasteur Mansion House

Fund, which has provided for the treatment in Paris of many English sufferers from the bites of rabid dogs, some of the members of the Committee of that Fund, as well as of the Mansion House meeting at which it was inaugurated, knowing the importance to the community of having a similar institute in Great Britain, determined to make an effort to establish the same.

A survey of the conditions under which bacteriology is practised in Great Britain is sufficient to show at once the pressing need of creating a centre of the kind, since, although several medical schools and Universities have provided for the teaching of bacteriology to a degree suitable for diplomas in public health medicine, and although in the laboratories of the College of Physicians and Surgeons in Edinburgh, and of the conjoint London Colleges, besides those of University College, King's College, and the College of State Medicine, there is room and provision for a certain amount of original work, still it is quite notorious that the majority of original investigators are driven to go to Paris and Berlin, not only on account of the splendid collection of material and freedom of experiment there, but also for lack of sufficient accommodation in the laboratories of the United Kingdom. To remedy this state of things, and to provide an establishment which would greatly assist the medical schools and technical education generally, is therefore the object of the promoters of the British Institute of Preventive Medicine. The development of the scheme has now arrived at a very interesting point, which, as usual in this country, resolves itself into a contest between the friends and enemies of science. The object of the Institute being purely charitable and scientific, it was from the outset necessary to give its constitution a firm basis, in order to obtain the confidence of the public from whom naturally the cost of creating the Institute is to come. It has therefore to be incorporated, and such incorporation can practically only be obtained by permission of the Board of Trade, which grants leave for the registration of such institutes as limited companies, the word limited being omitted, thus insuring the appropriation of the funds for none but purposes identical with the original object for which they were intended. The Executive Committee of the British Institute, therefore, made through their solicitors, Messrs. Hunter and Haynes, the formal application for such registration to Sir Michael Hicks Beach, the President of the Board of Trade. To their surprise Sir Michael refused to register the Institute, and this without assigning in his letter any reason for his refusal. It is, however, understood that he has done so in consequence of his having received petitions from a few bodies of anti-vivisectionists, among whom are to be found as usual certain names, mostly ecclesiastical, of gentlemen whose intentions, however admirable, are dictated by absolute ignorance of the questions which they presume to discuss.

We understand (though it is incomprehensible how a Minister should have allowed himself to be placed in such a false position) that Sir Michael Hicks Beach alleges privately that by registering the Institute, a portion of the work of which will naturally include experiments on animals, he will be encroaching on the duties of the Home Office, to which department alone, however, as a matter of fact, is intrusted the administration of the utterly incompetent and harassing so-called Vivisection Act. Nothing can excuse the confusion of mind or ignorance which is thus displayed by an official of the Government, for, as is evident to the merest tyro in law, the question of experimental science has nothing whatever to do with the matter submitted to the Board of Trade. That body has only to make sure that the funds of the Institute cannot in the future be misappropriated to any other object. That is all it is asked to do, and that solely in the interests of the public.

The official seal of the Board of Trade having thus been given to stamp the Institute with the character designed for it by its promoters—namely, that of a charitable and not a commercial undertaking—it would then, of course, be necessary for the Executive Committee to apply to the Home Office for the registration of the Institute as a place where experimental science may be carried on.

With this second registration the Board of Trade has nothing whatever to do, and by taking upon himself the duty of considering this part of its constitution, the President has gone out of his way to raise difficulties in the formation by private individuals of a National Institute, which in other more intelligent and far-seeing countries the Governments have hastened to take the initiative in establishing and liberally supporting.

It is evident that Sir Michael Hicks Beach has been greatly misinformed on this matter, and we look forward with interest to the result of the representations of a very powerful deputation which we learn is to wait upon him on Friday, June 5, at 11 a.m., and which, constituted as it is of distinguished men in all branches of science, as well as of those of the general public who are interested in philanthropic sanitary measures, will point out to him the real facts of the case on which he has to adjudicate, and rescue the question from the erroneous position which it now occupies, owing to his unfortunate readiness to listen to the calumnious assertions of the haters of science and progress.

It is not difficult, we believe, to read between the lines in such a case as this. No beings are more human than Ministers and members of Parliament, or, in fact, all those whose own position or that of their party depends upon popular clamour. Such unfortunates listen like Eve with a fatal fascination to the voice of the deceiver, but, with a taste less worthy than hers, the fruit which attracts them is not that of the tree of universal knowledge, but of the ballot-box. They have hitherto laboured under the mistaken impression that an energetic and noisy group of agitators, leading in their train a few unscientific quasi-public men, were an important political body, and they consequently sacrifice to their misrepresentations the liberties of science and the good of commerce. The day is coming, or is rather come, when the scientific and cultured world will refuse to submit any longer to such a condition of affairs, and when all its branches, physiologists, agriculturists, chemists, engineers, medical and legal men, will unite in a compact body for the protection of their common interests, and we rather welcome the present difficulty, which has served to bring prominently forward the spirit animating them, and which no administrator will do wisely in failing to recognize.

THE GEOLOGY AND PHYSICAL GEOGRAPHY OF NORTH SYRIA.

Grundzüge der Geologie und physikalischen Geographie von Nord-Syrien. Von Dr. Max Blanckenhorn. Mit Zwei Karten, &c. (Berlin: Friedländer, 1891.)

IN this excellent treatise the author presents the reader with a synoptical view of the results of his observations over a region but little known; referring to his previous essays on the geology, palæontology, and petrology of North Syria for fuller details. The region described extends from the northern slopes of the Lebanon to those of the Taurus Mountains, and from the Mediterranean coast to the banks of the Euphrates and the ruins of Palmyra, embracing an area of about 45,000 square miles. It also includes the whole of the Orontes Valley and the Kurdish Mountains. The mountainous tracts immediately to the south have already been ably described, as regards their physical structure, by Carl Diener, in an essay which was favourably reviewed in NATURE at the time of its publication in 1886, and these observations on the geology of the Lebanon and Hermon have been taken up and extended by Dr. Blanckenhorn to the borders of Asia Minor. Still further south, we have the geology of Palestine illustrated and described by Fraas, Lartet, Tristram, and the officers of the Palestine Exploration Fund, extending into Edom and Moab and the Sinaitic peninsula; so that, as far as it is possible for travellers to carry out such a work as that of the geological portraiture of the region, we have now the whole tract from the shores of the Red Sea to the Taurus Mountains very fully described and illustrated. Two maps on a large scale, one showing the topography, the other the geology, accompany the present work. That there should be uncoloured spaces at intervals in the latter was inevitable, and is a proof of the caution exercised by the author in its preparation. The text itself also contains numerous geological sections and illustrations.

In comparing the geological structure of the Lebanon, as described by Diener,[1] with that of the range between the valley of the Orontes and the coast, called Djebel Ansârige (Nusairier-gebirge), the author observes that the representatives of the Upper Jura and Cenomanian lying at the base of the Lebanon formations are absent in the more northerly tracts, the lowest beds of the series being represented by the "Rudisten-kalk," of probably Turonian age. The engraved longitudinal section which the author gives to illustrate this, amongst other physical features, is drawn from the coast at Latakia (Lâdikije) over Dj. Hassan Erai to the Orontes at Mischalûm, and is of much interest as illustrating the general structure of this part of Northern Syria. The valley of the Orontes is shown to be in the line of a great fault, or system of faults, by which the Eocene limestone beds are "thrown down" along the eastern side of the valley against the older Cretaceous strata, which are elevated into the ranges of Dj. el Ansârije and Hassan Erai, capped by the same Eocene limestones which form the bed of the Orontes, but at a difference of relative level of about 1600 feet. On the eastern side of the valley the Eocene strata rise into high ridges, partly by the aid of a N.-S. fault, which is not improbably a continuation of the "great Jordan-Arabah fault," which has produced such remarkable effects in connection with the physical structure of Palestine and Arabia Petræa.[1] The position of this fault seems also to be indicated in the section across the Orontes at Hammâm Sheikh Isa, illustrating the region of Mons Cassius.

The author gives a graphic description of the gorge of the Orontes in the neighbourhood of the hot springs (Hammam) above the great bend which the river takes from its northerly course towards the west in order to reach the Mediterranean. At Djisr esh-Schughr the river enters a cañon which has been worn down to a depth of 160 metres in beds of Eocene limestone and marble rich in Nullipores, and amongst the massive Miocene limestone (Grobkalk); while to the left rises the plateau of Dj. el Koseir, breaking off in successive terraces towards the Orontes Valley, and on the right the crest of Dj. el 'Alâ. On leaving this gorge the river enters an extensive alluvial plain, making a magnificent sweep round to the westward; and in its course through a rocky and broken country bathes the ruined walls of Antioch, the once famous capital of Syria—a city which bears so honourable a place in the early history of Christianity.

The region of Northern Syria physically divides itself into three distinct regions which are adopted for purposes of description by the author. The first includes the coast ranges; the second, the depression lying to the east of these, including the valleys of the Orontes and the Kara sea and river; the third, the "Hinterland," or interior tracts of North Syria lying to the east of the depression, and including the Khurdish Mountains: we can only here specially notice this last. This region is remarkable for the great tracts of Miocene strata, reposing sometimes on those of Eocene, sometimes on those of Cretaceous, ages of the Palmyrene wilderness and of Anti-Lebanon, and which are in turn largely overspread by great sheets of plateau basalt. Of these Miocene strata the plains round Aleppo are chiefly formed. Here they are nearly horizontal, but towards the north they are tilted, and the Eocene and Cretaceous strata again rise to the surface and terminate in the escarpment of Kardalar Dagh, beyond which rises the high plateau of Kâwâr, and still further towards the north-west the lofty ridge of Giaur Dagh, which reaches an elevation of 1330 metres. This latter is formed of Devonian limestone, slate, and grit, which appear to be the fundamental rocks of this part of Syria. The plateau of Kâwâr, which intervenes between the Giaur Dagh and the Kurdish ranges, is formed of gabbro, norite, schillerfels, and serpentine, of an age intervening between the Upper Chalk and the Eocene. The Miocene strata which occupy so extensive a part of Northern Syria were formed, according to the author, under the waters of an arm of the Mediterranean, which extended inwards at the base of Dj. el-Koseir beyond the Kuweik and the vicinity of Aleppo, bounded by irregular ranges of emergent hills of Eocene and Cretaceous strata. The formation consists of basal conglomerates of flint pebbles, passing into calcareous sands, clays, and finally the massive limestone (Grobkalk) already referred to, and has yielded forms of *Operculina*, *Clypeaster*, &c., clearly indicating its marine origin. This epoch was remarkable for the display of volcanic energy on a vast scale. Great sheets of augitic lava, together with tuff and agglomerate, were erupted during the Miocene epoch, not only in Northern Syria but in the East Jordanic region to the south, and were again renewed in Post-Pliocene times. It is probable that to volcanic action we must refer the origin of some of the peculiar little lakes of Northern Syria, such as those of Homs and Kara, one occupying the bed of the Orontes, the other that of the Kara, where the ground probably fell in and became filled with water. The Pliocene period is represented by both marine and freshwater strata, deposited in bays and depressions along the margins of uprising lands, formed of all the older formations, including those of the Miocene period. All of these had been disturbed, upraised, and partially eroded before the deposition of the Pliocene strata. In this, as in other physical phenomena of Northern Syria, we are reminded of those of Palestine and Egypt. Throughout all this region the Nummulitic and Cretaceous strata were disturbed and upraised into dry land, and subjected to extensive denudation at the close of the Eocene and again at the close of the Miocene epochs, so that the stratigraphical continuity of these Tertiary formations has been repeatedly broken.

[1] "Mem. on the Physical Geology and Geography of Arabia Petræa, Palestine, &c." (Palestine Exploration Fund), 1886, pp. 103-12.

It may be worth while, in conclusion, to glance at the points of analogy, as well as of difference, between the physical conditions of Syria and of the region to the south of the Lebanon. In Northern Syria, and along the ranges of the Taurus and Anti-Taurus, the fundamental rocks on which are superimposed the great calcareous formations of Cretaceous and Tertiary ages consist of Devonian schists, greywacke, and limestone,[1] together with masses of various igneous rock. In Southern Palestine and the Sinaitic peninsula, on the other hand, the fundamental rocks consist of granite, gneiss, various crystalline schists of Archæan age, traversed by innumerable dykes of hornblendic, augitic, and felspathic rock; surmounted at intervals by Lower Carboniferous beds; this is a remark able contrast. But a still greater, perhaps, is to be found at the next stage. All along the eastern border of the Jordan Valley, south of the Sea of Galilee, extending southwards along the table-land of Moab, Edom, and the Arabah Valley, as well as through the Sinaitic peninsula, and into Upper Egypt, the base of the Cretaceous series is represented by the Nubian sandstone,[2] a formation of great persistency, and interesting from an architectural point of view for its extensive use as a building-stone in the great structures of Ancient Egypt; as, for example, in the colossal figures of Amenophis in the plain of Thebes, as also in the temples and sepulchres of Petra. This formation appears to be altogether wanting north of the Lebanon, where, according to Herr Blanckenhorn, the Cretaceous strata of the Turonian stage are the lowest of the series.[3] The points of contrast, however, here terminate; for over the whole region from Upper Egypt and the Libyan Desert on the south to the Taurus Mountains on the north, a distance of 1000 miles and beyond, the Cretaceous and Eocene limestones were deposited, and formed part of the floor of the ancient ocean, the original limits of which it is hard to determine with any approach to accuracy.

At the close of the Eocene epoch this ocean bed was subjected to powerful movements. Large tracts, including the Libyan Desert and Egypt, Palestine and Syria, were elevated into dry land; while the strata were bent, folded, and faulted along lines ranging generally from north to south. To this period is to be referred the production of the great Jordan-Arabah fault, which has now been traced at intervals from the Gulf of Akabah to the valley of the Orontes, a distance of over 350 miles, while the main features, especially the mountains, had the outlines which they now present marked out. During the Miocene period, along with a partial re-submergence, volcanic action came into play over a region generally bounded by the Jordanic depression on the west, and extending from the Arabian Desert to the base of the Taurus, and the head waters of the Euphrates. In Northern Syria, extensive sheets of basaltic lava are found west of the Orontes Valley, as well as at Antioch, Aleppo, and other parts. At a later period, bordering on the present, fresh eruptions were added. The region we have been considering has its natural boundary towards the north in the Taurus range, where a system of E.–W. flexures take the place of those of the region to the south, where (as we have seen) the prevalent direction of the flexures is meridional.

EDWARD HULL.

EUROPEAN BOTANY.

Plantæ Europeæ: enumeratio systematica et synonymica plantarum phanerogamicarum in Europa sponte crescentium vel mere inquilinarum. Autore K. Richter. Tomus I., pp. 378. (Leipzig: Verlag von Wilhelm Engelmann, 1890.)

WHAT is most wanted in systematic botany at the present time is a general flora of Europe, worked out for the different countries on one uniform plan, with the sub-species and varieties placed in their proper subordination under the primary specific types, and the synonyms worked out carefully. The number of plants in Europe is about the same as in the United States. For these Asa Gray planned a general flora in three volumes, of which the middle one, containing the Gamopetalæ, was published shortly before his death, and the first and third left in a forward state of preparation. Many years ago Mr. Bentham planned and carried out, with the assistance of Baron von Mueller, a complete flora of Australia. There are 40 or 50 per cent. more plants in India than in Europe. Sir Joseph Hooker's "Flora of British India," containing descriptions and full synonymy of every species, has reached the end of the Dicotyledons, and in the last part the Orchideæ are finished, so that five-sixths of the work is now done. There is, however, no such book in existence as a general descriptive flora of Europe. For Europe the difficulty lies far more in the bibliography than in the plants themselves. An enormous number of subordinate forms have been described under specific names, and the number of channels of publication in the way of journals and reports of societies becomes greater and greater every year. Nyman's "Sylloge," published in 1854–55, and his later "Conspectus," have been a great boon to all European workers. Though they do not contain any descriptions, they give a tabular view of the whole European flora, tracing out in detail the geographical distribution of the species; and in the "Conspectus" especially, great pains has been taken to separate the subordinate from the primary types. The present work, like Nyman's, does not contain any descriptions. It deals with the geographical range of the species much more briefly, indicating it within the compass of a single line. Its strong point is bibliography, and it gives under species a list of all the names that have been applied to it by different authors, with a citation of the book and page where each name is published, with a note of the date of publication. The plan followed can be best illustrated by an example, and the following is the way in which the cultivated wheats are dealt with:—

Cultum.

Of course it is impossible for an author covering such a wide field to work out for himself all the details, and in the critical genera, such as Potamogeton, Festuca, Crocus, Iris, Tulipa, and Narcissus, no two authors are ever likely to agree as to which should be classed as primary, which as subordinate types, and which as mere synonyms. The present portion of the work includes only the Gymnosperms and Monocotyledons. The author admits 250 European genera, 1830 species, and 840 sub-species. He keeps up the oldest specific name published under any genus, not, as is usual in England, the name first published under the genus in which the plant is now placed. I find that a considerable number of books and papers published in England have not been taken into account; for instance, Maw's magnificent monograph of the genus Crocus, C. B. Clarke's monograph of the European species of Eleocharis in the *Journal of Botany*, 1887, p. 267, and Arthur Bennett's work on Potamogeton, as summarized in the last edition of Hooker's "Student's Flora." The book has cost great care and pains, and will be found very useful by all who work at European botany.

J. G. BAKER.

OUR BOOK SHELF.

The Missouri Botanical Garden. 8vo, with several Maps and Engravings. (Printed for private circulation by the Managers, 1891.)

THE Missouri Botanical Garden is situated at the city of St. Louis, and was founded by the late Henry Shaw. He was born at Sheffield in the year 1800, and emigrated to Canada with his father at the age of eighteen, and a year later moved southward to St. Louis, which was then a small isolated French trading post. He established himself in business as a dealer in cutlery, made a fortune of 250,000 dollars by the time he was forty years of age, and then retired from business. In 1840 he visited Europe for the first time, and in 1842–45 made a three years' tour in the Old World. In 1851 he visited Chatsworth, and particularly admired its garden and conservatories. This led him to entertain the idea of forming a large garden at home. One of the best American botanists, Dr. Engelmann, lived at St. Louis, and Mr. Shaw sought his help and advice. In 1857 he opened a correspondence with Sir William Hooker. He engaged from the Royal Botanic Garden in Regent's Park Mr. James Gurney to superintend the carrying out of his plans. He died in 1889, and bequeathed to his trustees 760 acres of land, situated partly within and partly outside the limits of the city of St. Louis, to be kept up as a Botanic Garden open to the public, containing a museum and library.

On the recommendation of Dr. Asa Gray, Mr. William Trelease, who was then Professor of Botany in the Wisconsin University at Madison, was appointed in 1885 Director of the Garden, a post which he still holds, and provision was made for the establishment of a school of botany and the endowment of six scholarships for garden pupils, each worth 300 dollars a year, with free lodging and free tuition.

The present volume contains a biographical sketch of the founder of the Gardens; a copy of his will; of the Act that was passed to enable him to convey the land to the trustees, and of the deed of gift for the endowment of the School of Botany; a copy of the inaugural address by Prof. Trelease, when the School of Botany was founded; also of the first annual report of the Director; of the proceedings at the first annual banquet of the trustees, to which a large number of eminent men of science and other guests were invited; and of the first annual flower sermon, which was preached in Christ Church Cathedral on May 18, 1890, by the Bishop of Missouri. The book is illustrated by plans of the garden, a large number of views of the museums and other buildings, including Mr. Shaw's house and a fine statue of Humboldt.

Everything is now in full working order, and we have just received from Prof. Trelease a capital synopsis of the American species of the difficult genus Epilobium, containing full botanical descriptions and figures of all the species. The herbarium now contains about 20,000 mounted sheets of flowering plants and ferns, also a large collection of Fungi and other Cryptogamia.

J. G. B.

Géologie: Principes—Explication de l'Époque Quaternaire sans Hypothèses. Par H. Hermite. Pp. 145. (Neuchatel, 1891.)

ON taking up this little book the geological reader is at once struck by the words "sans Hypothèses" in the title. A volume on Pleistocene geology free from hypotheses would seem to him to usher in a new era in geology, and would be most heartily welcomed by him. The title of the present work, however, is misleading; the book is almost entirely devoted to theoretical explanations of purely hypothetical facts. We have not space to notice in detail the various subjects of which the author treats, but as an example of his method we may point to his "Origine des Pluies Quaternaires" (p. 39). In this section he accepts the hypothetical Quaternary "Pluvial Period"—which, by the way, seems to have been characterized by a singularly poor aquatic fauna and flora—and he then accounts for the supposed excessive rainfall during Tertiary and Quaternary time by the amount of vapour thrown out by volcanoes, adding that the small rainfall of the Secondary periods is accounted for by the absence of volcanic action during those periods! Then we meet with our old acquaintance the former excess of carbonic acid in the air and its influence on the ancient climate of the polar regions—possibly correct, but certainly hypothetical. Further on, speaking of the origin of the continental platform at a depth of 200 mètres, the author states that this feature results from the raising of the general level of the sea from the melting of the Quaternary ice; and from this hypothetical raising he arrives at the result that the mass of the Quaternary ice corresponded to the total mass of the sea now lying above the level of the continental platform. Another speculation relates to the breaking through of the Indian Ocean across Siberia to the Polar seas, thus causing a milder climate, and accounting also for the parallel roads of Glen Roy and the terraces in Norway and Greenland. We cannot pretend to follow the reasoning, but it is all somehow connected with the author's theory "qu'à une diminution de la densité des mers correspond un abaissement de leur surface."

C. R.

Webster's International Dictionary of the English Language. Revised and Enlarged under the Supervision of Noah Porter, D.D., LL.D. (London: George Bell and Sons. Springfield, Mass. U.S.A.: G. and C. Merriam and Co.)

WEBSTER'S Dictionary is so well known on both sides of the Atlantic that it is unnecessary to do much more than note the appearance of the present edition. The work was published originally in 1828, after which it was steadily improved in successive issues. It has now been revised so thoroughly, and with the aid of so many competent scholars, that for popular use it can hardly fail to maintain the ground it has already won. Much prominence is given to "the definitions and illustrations of scientific, technological, and zoological terms," and in the preface to the English edition it is stated that no pains have been spared to make this part of the book "as perfect as possible in both text and illustration." The definitions in particular branches of science have been revised by such men as Prof. H. A. Newton and Prof. E. S. Dana—names which are a sufficient guarantee for the way in which the task has been accomplished. In the department of etymology, Prof. E. S. Sheldon, of Harvard University, has carefully dealt with the results presented in the last edition, bringing them into accord with the philological ideas of the present day. The pictorial illustrations are numerous, and well adapted to the purposes for which they are inserted.

Elementary Chemistry; for Beginners. By W. Jerome Harrison, F.G.S. (London: Blackie and Son, 1890.)

THIS volume of 144 pages consists of an expansion of the author's notes of lessons prepared for teaching children from nine to thirteen years of age according to the outlines given in the education code. The information is conveyed in familiar language, and each chapter closes with a series of questions which are well calculated to test the child's progress. It is a pity to issue any book that deals with scientific matters without a contents table and an index, and we fear that the absence of these in the present case will lead to inconvenience. And we would suggest that the quantities selected for the examples might approximate more closely to those most generally employed. The hydrogen from the use of a ton of zinc, the preparation of 1000 lbs. of carbon dioxide, eighteen quarts of oxygen mixed with an equal volume of hydrogen and exploded, ten gallons of hydrogen mixed with half its volume of chlorine and exposed to sunlight, indicate experiments on an extravagant if not an appalling scale. These, however, are matters of detail. The notes of so successful a teacher as Mr. Jerome Harrison cannot fail to be valuable to others who are engaged in a like work as well as to the students themselves.

Examination of Water for Sanitary and Technical Purposes. By Henry Leffmann, M.D., Ph.D., and William Beam, M.A. Second Edition. (London: Kegan Paul, Trench, Trübner and Co., Ltd., 1891.)

THE fact that a second edition has been called for only two years after the issue of the first, shows that this excellent hand-book has been very generally appreciated. The authors have revised the work and made many additions to it chiefly of processes that have recently grown in importance. Among the principal of these additions, we observe that the three pages on "Living Organisms in Water" of the first edition are now expanded into a chapter of thirteen pages entitled, "Biological Examinations." A table of culture phenomena of some of the more important microbes is given. But concerning this matter the authors state that "until pathogenic microbes are more clearly indicated and described, the methods will be of little use in dealing with the problem of the determination of the sanitary and technical value of water supplies."

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The University of London.

I DO not wish to criticize in the least Prof. Lankester's valuable statement in your last issue, with which I entirely agree; but I desire to point out that unless some energetic action is taken very soon we are likely to be farther than ever from the ideal which he has in view—namely, the establishment of a strong professorial University in London. The only scheme at present in the field is that put forward by the Councils of University and King's Colleges in the proposed charter for an Albert University.

This scheme has never met with the cordial support of a large section at least of the teaching staff of University College, and for the very obvious reason that it does not constitute a professorial University, but creates a new examining body on which the two Colleges will be, in the beginning at any rate, largely represented. The Albert University charter would create a second Victoria University in London. Now, both Mr. Dyer and Prof. Lankester are agreed that we do not want a federal University like Victoria in London; but they seem to forget that this pettifogging excuse for a University—a scheme drafted by bureaucratic rather than academic minds—is the only scheme in the field, and that, further, the Lord President of the Council has determined to hear by counsel, on an early day in June, what can be said for and against this scheme. It is further rumoured that the Burlington House Senate intends, after its recent discomfiture, to remain absolutely neutral. The danger, then, that we shall have a repetition in London of the difficulties of Manchester is a very immediate one. Let me point out exactly the anomalies of the Albert scheme. In the first place, it does not create a teaching University, but a new examining body. The University as such will have no control over the appointment of the professoriate either at University or King's Colleges, it will have no funds to dispose of, and there will be nothing to prevent rival second-rate teachers and teaching equipment instead of first-rate central teaching and central laboratories. For example, at the present time, putting aside the Central Institute, we have some half-dozen second-rate physical laboratories in London, but not a really first-class one worthy of a modern University among them. So long as there is competition between the Colleges, so long as they possess a double staff competing at every turn with each other for students' fees, this is unlikely to be remedied. Prof. Lankester speaks of a *union* of King's and University, and talks about their *combined* resources. The fusion of these two Colleges would certainly be the first stage to a true professorial University in London, but there is nothing in the Albert charter to bring this about: it unites the two Colleges not for teaching but for examining purposes. But what is still worse, while these two Colleges will remain autonomous, the Albert charter proposes to admit any further autonomous bodies, the teaching of which can be shown to have reached a certain academic standard. These bodies will not be absorbed, but their independent staffs will be represented on the Faculties and Senate. Here we have in fact the University of London over again,—at first composed almost entirely of the two Colleges, afterwards embracing all sorts and conditions of institutions in London, and ultimately open to every isolated text-book reader in the universe. It cannot be therefore too strongly insisted upon that the Albert charter, if granted, will not call into existence a professorial University, but federate a group, and an ever-widening group, of competing institutions for the purposes of *examination*. If it sheds for a time any additional lustre on the teaching staffs of the two Colleges—which I am much inclined to doubt—it will not achieve, what most of us have at heart, the establishment in London, at any rate in the germ, of a great University in the Scottish or German sense. A University, on the scale we hope for, would *absorb* the plant of University and King's Colleges, of the Royal College of Science, and of the Central Institute without the least difficulty. With the death or transference of existing teachers, whose pecuniary interests would have of course to be carefully safeguarded, special branches of higher teaching and research might be localized at these various centres,[1] and we thus might reach in the future an efficient University organization in London. This may indeed be considered a merely ideal future, but any scheme like the proposed Albert University, which will only impede its ultimate realization, ought to meet with strenuous opposition from those who believe that a great professorial University must sooner or later be established in London.

The difficulty as to the granting of medical degrees will for long be the stumbling-block of any scheme, but the true way to surmount it seems to be that suggested by Prof. Lankester—namely, the complete divorce of the clinical teaching at University and King's Colleges from the science teaching, and the establishment of separate clinical schools at the existing College hospitals on precisely the same footing with regard to the University as the other medical schools. The preliminary science teaching at the various medical schools might then be safely intrusted to University readers, who might continue to be, as they now largely are, peripatetic. These readers would naturally belong to the science faculty of the new University, and if largely paid by students' fees might be trusted to safeguard the "preliminary scientific interests" of the medical schools. It seems to me, therefore, that some vigorous effort ought to be made to obtain the modification of the Albert University scheme in the sense indicated by the following proposals:—

PROPOSALS *in re* TEACHING UNIVERSITY.

No scheme for the constitution of a teaching University in London will be satisfactory which does not:

1. Place the appointment of the teaching staff, as well as the control of laboratories, libraries, and buildings, in the hands of a single executive body, hereinafter spoken of as the new University Senate, or of bodies, such as Faculties or boards of study, to which it may delegate its powers.

2. Confer on the new University Senate the power of granting degrees in all Faculties, including that of Medicine.

3. Give to the teaching staff an immediate representation of one-third, and an ultimate representation of at least one-half, on the new University Senate.

These conditions would probably be best fulfilled by:

4. The immediate fusion of the Councils of University and King's Colleges, and the Council or Governing Body of any other institution doing work of admittedly academic character in London, which may be willing that its laboratories and equipment should be placed under the control of the new University Senate.

[This would remove any ground from the objection that the two Colleges are claiming powers which they are not willing to share with the Royal College of Science or the Central Institute. It provides for these latter coming into the scheme on the same terms, if that is possible.]

5. The granting of a Charter to a body consisting of these combined Councils together with representatives of the teachers in the combined institutions.

6. The constitution of the new University Senate in the following manner:—

A. Immediate constitution—
   (1) The fused Councils of King's and University Colleges or their representatives.
   (2) The Councils of other academic bodies in London willing to be absorbed, or their representatives.
   (3) Representatives of the teachers to the extent of one-third of the total number.

B. Ultimate constitution—
   (1) University professors, either as *ipso facto* members or as representatives of the body of professors.
   (2) Representatives of the Faculties (*i.e.* of the readers and professors of each Faculty).
   (3) Co-optated members, not to be selected from the teaching staff.

   And possibly,

   (4) Representatives of bodies willing to endow professorships in the new University, or to hand over to the control of the University existing professorships or lectureships, *e.g.* (*a*) the Corporation of the City and the Mercers' Company as trustees of Sir Thomas Gresham's estate; (*b*) the Inns of Court—provided these bodies are willing to attach the Gresham Lecturers and the Readerships instituted by the Council of Legal Education to the new University.
   (5) Representatives of the Medical Schools and Royal Colleges of Physicians and Surgeons other than those selected by the Medical Faculty. This would only be a matter for consideration when the power to grant medical degrees became actual.

7. The transition from the immediate to the ultimate constitution of the new University Senate in the following manner:—

   (*a*) By not filling up vacancies among the members contributed to the new Senate by the existing College Councils as such occur.
   (*b*) By the increase of professorial members and representatives of the Faculties.

---

[1] *Elementary* teaching in many branches might for local convenience be still carried on at several centres.

8. The suspension of the power to grant medical degrees until such time as the Senate of the new University shall have satisfied the Lord President of the Council that an agreement has been reached with the Royal Colleges and the chief London Medical Schools as to the terms on which medical degrees shall be granted.

9. Providing, on the repeal of the Acts of Incorporation of University and King's Colleges which would accompany the granting of the new Charter, special regulations for the control of certain portions of the endowments or of certain branches of the College teaching, which it may not seem possible or advisable at present to hand over without special conditions to the management of the new Senate. For example, the Department of Divinity at King's College.

10. Paying due regard to the pecuniary interests of existing teachers (many of whom depend entirely upon students' fees) in the appointment of future University professors or readers.

11. Offering those professors of the existing Colleges, who might be willing to surrender the title of College professor, that of University reader, but not creating the occupants of chairs in any of the existing Colleges *ipso facto* professors in the new University.

In this mere sketch I have said nothing as to how faculties and boards of study might be constituted or as to how the University should grant degrees, for these seem to me "academical" problems, *i.e.* problems to be thrashed out by the University itself when it is once incorporated. Objection will be taken to much of the above by many individuals, but I believe it foreshadows the direction in which the *only scheme at present under discussion* must be modified if it is to lead to the ultimate establishment of a great teaching University in London, and not to a mere organization of teachers for examination purposes.

KARL PEARSON.

IT seems to me that the force of the arguments of Profs. Lankester and Ramsay in last week's NATURE (May 28, pp. 76, 78), so far as they harmonize with each other, would have to be admitted, if the main object of a University were to foster that premature specialism, which, under the scholarship system, has already wrought great mischief to real education in this country, or to increase as far as possible the number of clever but half-educated specialists, with which a close acquaintance with any of the great scientific societies makes one only too familiar. The example of this has been well set by at least one of the great metropolitan day schools. The fatal weakness of the arguments referred to is that they ignore, as no University ought to do, the claims of general education. If the advancement of scientific research is really desired by University and King's Colleges, all they have to do is to institute on their own account a diploma of the nature of the Associateship of the Royal School of Mines or College of Science, and make the training for it so good and thorough that the possessors of such a diploma shall be such a *desideratum* in those "commercial" quarters to which Prof. Ramsay appeals as a sort of final authority, that they shall drive such creatures as B.Sc.'s out of the field. Special brain-power, highly developed, is no doubt a splendid thing in its way, and recognition of it in the field of science is fully provided for in the B.Sc. honours, and in the ultimate D.Sc. degree; but, in considering the terms on which a *degree* should be given, general education and culture cannot be left out of account. In Germany something of the sort is guaranteed by the examinations which have to be passed on leaving the gymnasium (or high school) before students proceed to the University to specialize; in England it has been found necessary to institute the matriculation examination. That need, however, is no longer so imperative as it was; and for my own part I see no real objection to the "leaving certificate" of the Oxford and Cambridge Examining Board being accepted in lieu thereof; for I speak of what I know, when I say that this carries with it a guarantee of as much education and culture as the Matriculation Examination does, and often a great deal more. I would only stipulate that it should include one modern language and one branch of science.

Prof. Ramsay has over-ridden his horse, by the emphatic preference he gives to a German degree. He is a comparatively young man; but some of us (who are not yet quite senile) can remember the time when the facilities for obtaining the German Ph.D. degree were such (they are such to this day in America) that the degree became a by-word and a reproach, and still carries with it suspicions altogether disadvantageous to those who have taken the genuine degree in Germany. This is surely a warning against the multiplication of small Universities in this country. Again, if the time-honoured Universities of Oxford and Cambridge are not proof against the temptation to swell the contents of the University chest by accepting fees for the silken degree of M.A., which in the eyes of the *vulgus* is supposed to represent higher intellectual attainments than the B.A., can we expect greater virtue in a small and brand-new University struggling to "make both ends meet"? Were any further illustration required of the way things would be likely to drift with small and independent degree-granting corporations, we might find it in the readiness with which the authorities of King's College threw over Latin two years ago in the mercantile department of their school (then in a state of depression), at the mere bidding of the Chambers of Commerce, although its retention had been advocated by two leading scientific men. The really inspiring motive of this agitation is, I think, astutely kept in the background. A. IRVING.

Wellington College, Berks, June 1.

ONE of the taunts most frequently levelled at the London University—or "Burlington Gardens," to use Prof. Lankester's favourite expression—by certain professors of University College and other advocates of a "teaching University in and for London" is, that the present University is a "mere examining board." The University has, it is true, a Brown Professor of Physiology and Pathology, who delivers annually a course of lectures relating to the studies and researches carried on at the Brown Institution. But this professorship is an exception, though the University, by accepting the Brown Trust, showed clearly enough that it did not recognize any obligation to abstain from appointing University Professors and Lecturers. We have been previously told that there was a "tacit understanding" at the foundation of the University that this should not be done. But Prof. Ray Lankester goes far beyond the assertion of a "tacit understanding." He talks of "pledges" given by the founders of the University being "falsified," and "most solemn obligations" violated—terrible crimes, which, however, have been committed already by the appointment of the Brown Professor. But how such "obligations" and "pledges," or even a "tacit understanding," could ever have existed, I fail altogether to see, for it was the expressed intention of the founders of the University that its powers and privileges should be the same as those of the Universities of Oxford and Cambridge. Testimony as to this pledge may be found in the evidence given before the recent Commission. The late Dr. Carpenter's view of this matter was stated by Mr. Dickins in his communication to NATURE. Convocation has, years ago, voted in favour of the establishment of University Professorships and Lectureships, though I do not in the least believe that the graduates would sanction any proposal involving that the University should prepare candidates for its examinations, or compete with the ordinary work of the Professors in University College and other similar institutions. Whether research is or is not carried on successfully at University College is a matter on which I express no opinion. But, however this may be, it should be remembered that the students of this College have become only a small fraction of the candidates for London degrees. It would be, it seems to me, in the public interest that the University should make provision for the encouragement and reward of those among the great majority of its members who show a capacity for research and a power to extend the boundaries of knowledge. That the University has only one solitary Professor is due, I believe, in great measure to the narrowminded and unwise jealousy of University College, and to the fear lest some endowments should chance to be diverted to the University.

Prof. Lankester abandons altogether the scheme set forth in the Draft Charter of the "Albert University of London." This Charter proposed the establishment of a University whose range of activity should extend over colleges or other institutions in an area with a diameter of thirty miles. Prof. Lankester's ideal University, which would still be federal, is to consist only of University and King's Colleges. These institutions have not as yet shown any disposition to amalgamate the one with the other, and such a disposition is not likely to arise. They are, in fact, founded on distinct principles. The motto of the one, if I recollect rightly, is *Cuncti adsint* and of the other *Sancte et sapienter*. Some time ago I heard of a Society of University

College students being compelled to meet elsewhere instead of in the College on account of there being something of a religious character connected with their meetings, while there are facts of a different character in the history of King's College which may be easily remembered. That a federal University consisting of institutions so dissimilar would work harmoniously I very much doubt. Probably the graduates of the existing University would care but little, except on general public grounds, about University and King's Colleges having power to grant degrees, if as a University they would assume a name not likely to be mistaken for that of the University of London. As yet the Victoria University is not a conspicuous success, and the London University examinations are still held at Owens College.

With the views set forth by Mr. Thiselton Dyer I should be disposed in great measure to agree, though there are some points on which I should have liked to make some remarks; but I fear, if I did so, I should trespass too far on your space.

London, May 29. THOMAS TYLER.

THOSE who have taken part in the interesting discussion on the University of London, in your columns, have all viewed the subject from the academic standpoint. Would it not be well to consider it also from another point of view, viz. that of the educational needs of London? Prof. Ramsay contends "that a University is primarily a place for the extension of the bounds of knowledge." It is surely more accurate to say that a University, under the conditions that now exist, has two main functions—the one the extension of the bounds of knowledge by research, and the other the wide diffusion of that knowledge. The purpose of such diffusion should be to afford, as far as possible, to every individual the opportunity of obtaining such a training as would qualify him or her to take part in the development of some branch of knowledge, or at any rate to follow with appreciation and interest the advance made by others.

It needs no argument to show that it would be for the advantage of research, and for the well-being of the community, that real University training should be as widespread as possible. Ability and bent for some special study may frequently not be developed until somewhat late in life, after a business career has been begun. There is scarcely a branch of science that does not owe much to investigators whose researches were carried on during hours spared from some bread-winning occupation. The late Prof. John Morris was in early life a chemist in the Borough; Dr. James Croll was for years the janitor of the Andersonian University, Glasgow; even in the very number of NATURE containing Mr. Dyer's letter, the case of M. Rouault, one of the pioneers in the geology of Brittany, is mentioned, who did his early work while carrying on the business of hairdresser. A University training would have been of inestimable value to such students as these (and there are hundreds of such, with capacity for good work, scattered over London and the country), but no provision is made for them in our existing system.

Surely the important question therefore is, What kind of University would discharge most effectively for London the duty of providing for the needs of every class of students? The University should clearly recognize all organized teaching of University rank, whether given within the walls of a specified College or not. One of the most urgent needs of London is a co-ordinating head for all its multifarious higher educational agencies. The only University that will really adequately meet the needs and stir the enthusiasm of Londoners will be a University in vital relation with and directing and controlling all the higher teaching of the metropolis. This would, no doubt, be a new type of University, but the changed conditions of these times necessitate large modifications in the constitution of our institutions. This is sufficiently illustrated by the fact that the University of London itself was a new type of University, as also was the more recent Victoria University.

The new teaching University for London should have as its accredited professors and lecturers the staffs of University and King's Colleges, the Royal College of Science, the various medical schools, and any other institutions of equal rank, and in addition a large staff of lecturers at work in different parts of the metropolis at convenient centres. It would be possible, by an extension of the principle admitted into the draft scheme for the re-constitution of the University of London, viz. that of requiring from every University teacher a syllabus of his course of teaching, and further, by making such syllabus the basis of the examination, to incorporate all the work done by the accredited teachers of the University into its curriculum for degrees. This would make it possible to open up a University career to evening students. While day students would complete their course of study in three or four years, evening students would take nine or ten, and the curriculum could without serious difficulty be modified to meet the conditions.

May 30. R. D. ROBERTS.

I WOULD ask whether it is quite fair to assume that, because Convocation has rejected the Charter proposed for the University of London, it therefore follows that that body is out of sympathy with the attempts that are being made to establish a "real University," whatever that may mean. Is it not possible that a large proportion of those adverse votes were recorded because there were elements in the scheme which were felt to be impracticable or open to serious objection? At all events, I feel sure that there are many who would refrain from regarding the vote as being an expression on the main issue.

The views so well put forward by Prof. Ray Lankester as to the undesirability of establishing what he terms federal Universities fully enlist our sympathies; but are we not sailing very near the wind in the suggestion that University and King's Colleges and "other institutions" should be incorporated on University lines?

I say, by all means avoid centralization and beware of the "never-ending Committees and schedules of such clumsily-organized Universities." But what of value is then left that University College does not already possess? Would the appropriate definition and allotment of degrees of all shades and grades have contributed one iota to the work and influence of Graham, Sanderson, Sharpey, Foster, Williamson, and Prof. Lankester himself, or have added to the benefit they have conferred upon University College? One does not surely regard the granting of degrees as an important element in the German University: its distinguished professors are not Berlin men or Strassburg men—they are pupils of Liebig, of Wöhler, of Bunsen, and the like; and its students are not regarded as graduates of Heidelberg or Giessen, but in like manner as pupils of so-and-so. And University College is, I take it, much more nearly in function a German University now than ever it is likely to be as a federal University. I verily believe that such is the taste of the so-called properly ordered English mind for schemes, plans, and organizations, that a governing body, even though largely composed of the most uncrystallizable elements, would shortly be found carefully hedging itself round (and the students) with that beautiful machinery which Prof. Lankester so heartily detests. Prof. Ramsay's association of "examination on the brain" with the London University undergraduate I fear does the said undergraduate an injustice, if it is meant to differentiate him from his fellows of the "real Universities."

The men who regard the College Calendar with its traditional questions as their *vade mecum*, and whose only other study is the idiosyncrasies of the examiner, are ubiquitous, and their name is legion. If I could think they were confined to the "Burlington Gardens University," I, for one, would vote against the alteration of one jot or tittle of the present organization, if only lest they might be disturbed from their resting-place there. G. H. BAILEY.

May 30.

Quaternions and the Ausdehnungslehre.

PROF. GIBBS' second long letter was evidently written before he could have read my reply to the first. This is unfortunate, as it tends to confuse those third parties who may be interested in the question now raised. Of course that question is naturally confined to the invention of methods, for it would be preposterous to compare Grassmann with Hamilton as an analyst.

I have again read my article "Quaternions" in the *Encyc. Brit.*, and have consulted once more the authorities there referred to. I have not found anything which I should wish to *alter*. There is much, of course, which I should have liked to extend, had the Editor permitted. An article on Quaternions, rigorously limited to four pages, could obviously be no place for a discussion of Grassmann's scientific work, except in its bearings upon Hamilton's calculus. Moreover, had a similar article on the *Ausdehnungslehre* been asked of me, I should certainly have declined to undertake it. Since 1860, when I ceased to be a Professor of Mathematics, I have paid no special attention to general systems of *Sets*, *Matrices*, or *Algebras;* and without much further knowledge I should not attempt to write in any detail about such subjects. I may, however, call attention to the facts which follow; for they appear to be decisive of the question now raised. Cauchy (*Comptes Rendus*, 10/1/53) claimed *quaternia* as a special case of his "clefs algébriques." Grassmann, in turn, (*Comptes Rendus*, 17/4/54; and *Crelle*, 49) declared Cauchy's methods to be precisely those of the Ausdehnungslehre. But Hamilton (*Lectures*, Pref. p. (64), foot-note) says of the clefs algébriques (and therefore, *on Grassmann's own showing*, of the methods of the Ausdehnungslehre) that they are "*included* in that theory of SETS in algebra . . . . . . announced by me in 1835 . . . . . . of which SETS I have always considered the QUATERNIONS . . . . . . to be merely a *particular* CASE."

But all this has nothing to do with Quaternions, regarded as a calculus "*uniquely* adapted to Euclidian space." Grassmann lived to have his fling at them, but (so far as I know) he ventured on no claim to priority. Hamilton, on the other hand, even after reading the first *Ausdehnungslehre*, did claim priority and was never answered. He quoted, and commented upon, the very passage (of the *Preface* to that work) my allusion to which is censured by Prof. Gibbs. [*Lectures*, Pref. p. (62), foot-note.] I still think, and it would seem that Hamilton also thought, that it was *solely because Grassmann had not realized the conception of the quaternion*, whether as $\beta\alpha$ or as $\beta\alpha^{-1}$, that he felt those difficulties (as to angles in space) which he says he had not had leisure to overcome. I have not seen the original work, but I have consulted what professes to be a *verbatim* reprint, produced under the author's supervision. [*Die Ausdehnungslehre von* 1844, *oder die lineale Ausdehnungslehre, &c. Zweite, im Text unveränderte Auflage. Leipzig*, 1878.] Prof. Gibbs' citations from my article give a very incomplete and one-sided representation of the few remarks I felt it necessary and sufficient to make about Grassmann. I need not quote them here, as anyone interested in the matter can readily consult the article.

In regard to Matrices, I do not think I have ever claimed anything for Hamilton beyond the *separable* ϕ, and the symbolic cubic (or biquadratic, as the case may be) with its linear factors; and these I still assert to be exclusively his. My own work in this direction has been confined to Hamilton's ϕ, with its square-root, its applications to stress and strain, &c.

As to the general history, of which (as I have said above) I claim no exact or extensive knowledge, Cayley and Sylvester will, no doubt, defend themselves if they see fit. It would be at once ridiculous and impertinent on my part were I to take up the cudgels in their behalf. P. G. TAIT.

The Spinning Ring.

I CANNOT suppose that the mathematicians are all in error; but venture modestly to ask what are the assumed conditions under which a girdle round the earth at the equator would be subject to strain. If the surface of our globe at the equator were continuous and level land, about 30,000,000 of persons—more than 1000 to a mile—standing at equal distances and joining hands, would form a girdle without any strain, or the girdle might be formed of separate pieces of wire placed end to end in close contact, which, if afterwards soldered, would form a girdle, without strain.

Then, it is stated, in NATURE, vol. xliii. p. 514, that a wire girdle supported on poles, if "relieved from gravitation," but acted upon by a (greatly augmented) "centrifugal force *equal* to the cable's weight"—that is, by an equal force acting in the opposite direction—would be subjected to a 20-*fold* strain. Why? REGINALD COURTENAY.

4 Serjeants' Inn, Fleet Street, April 30.

BISHOP COURTENAY'S questions may perhaps be clearly answered as follows. The centrifugal force of a free spinning hoop has to be balanced by its peripheral tension; but this, having a large tangential and a small radial component, acts at a disadvantage, and may have to be very big to balance even a moderate centrifugal force. The larger the hoop the more marked is the magnitude of the tangential component as compared with the radial or effective component; so that a hoop 8000 miles in diameter could not rotate even once a day without tearing itself asunder.

An actual girdle round the earth is not dependent on peripheral tension for balancing its centrifugal force, since it is subject to an overpowering centripetal force due to the earth's gravitation.

The statement made by Mr. Herschel on p. 514, vol. xliii., involved not a 20-fold stress but a 20-fold speed, which means a 400-fold stress. OLIVER J. LODGE.

The Use of Startling Colours and Noises.

LAST January a friend showed me a smew (*Mergus albellus*) shot on the Dee, near Chester, the crop of which he had found to be full of young flat-fish. He called attention to the dazzling whiteness of the bird's breast, and suggested that it must frighten the fish, and so be a disadvantage to it. A little consideration showed that the effect would be precisely the reverse. As long as the flat-fish remains at rest, its colouring assimilates so closely to the sand on which it lies, and with which it partly covers itself, that it would not be easily seen by the smew. But if, startled by the white object flashing down on it from above, it moves, it is seen at once, and of course captured. Anybody who has ever collected small insects, such as beetles, will admit the truth of this at once.

The same effect is probably produced by the hooting or screaming of owls when hunting at night. A mouse, which would be invisible even to the sharp eyes of an owl when motionless, would be seen at once if startled into motion by the sudden "shout" of the bird, whose noiseless flight had brought it unperceived into close proximity.

Perhaps these suggestions may serve to explain other apparent difficulties in the way of natural selection.

The brown owl hoots throughout the winter here, so that it cannot be a sexual call. ALFRED O. WALKER.

Nantyglyn, Colwyn Bay, May 25.

The Formation of Language.

I PERCEIVE that my note on the evolution of speech in the case of one of my children has excited some interest and called out communications both to myself and to you; but I must trespass again on your kindness to explain that what I considered noteworthy in that case was not the invention of words, which is not of rare occurrence, but the, to me, far more important phenomenon of the evolution of the habit of speech through the three stages, so distinctly marked in this case—of simulation, the faculty we share with the monkey, and which does not imply the possession of the idea; of invention of symbols, which indicates the birth of the power of conception, and perhaps the formation of what Max Müller calls "concepts," and the perception by the young mind of a community of interest and intelligence; and, finally, the faculty of learning from others ideas already formed, or what must be considered the germ of science: and it was the clear demarcation of the three states which interested me more than the mere invention of words. And this interest is the greater as the case appears to illustrate a law that the development of the individual follows the lines of the universal, so that the child but repeats, in a very much abbreviated sequence, what humanity had gone through as a whole. My purpose in bringing the case before your readers was rather to invite the repetitions of my observations with a view to the establishing of the law, than to publish an isolated phenomenon. W. J. STILLMAN.

Rome, May 8.

Cordylophora lacustris.

IT will be interesting to zoologists to know that Prof. Weldon recently found very large quantities of *Cordylophora lacustris* on submerged roots and stems in the Rivers Ant, about Ludham Bridge, and Thurne, at Heigham Bridges, Norfolk. From my own knowledge, I can say that it is very generally met with throughout the whole system of rivers and broads in connection with the Bure. At the places spoken of, a fresh-water tide of from 6 to 18 inches is felt. I think I am safe in saying that a salt tide has but once been known so high up these rivers.

JOHN BIDGOOD.

7 Richmond Terrace, Gateshead-on-Tyne.

ON SOME POINTS IN THE EARLY HISTORY OF ASTRONOMY.[1]

IV.

FROM what has been stated it is not too much to assume that the Egyptians observed the sun on the horizon. This being so, the chances are that at first they would observe the stars on the horizon too, both stars rising and stars setting; and that is rendered more probable by the very careful way in which early astronomers defined the various conditions under which a star can rise or set, always, be it well remembered, in relation to the sun. They spoke of a star as rising or setting achronically, heliacally, or cosmically.

The cosmic rising meant that the star rose, and the cosmic setting meant that the star set, at the same moment as the sun—that is, that along the eastern horizon we should see the star rising at the moment of sunrise, or along the western horizon a star setting at the moment of the sun setting. The achronical rising is different from the cosmic in this respect—that we have the star rising when the sun is setting and setting when the sun is rising. Finally we have the heliacal rising and setting; that is taken to be that the star appeared in the morning a little in advance of the sunrise, or set at twilight a little later than the sun. The following table from Biot[1] should make matters quite clear :—

Star at eastern horizon. ...	Rising. ...	Morning. ...	True or cosmic.	Sun rising.
			Apparent or heliacal.	Sun not yet risen, but depressed below horizon sufficiently to enable the star to be seen.
		Evening. ...	True or achronic.	Sun setting.
			Apparent or heliacal.	Sun just set, and depressed below horizon sufficiently to enable the star to be seen.
Star at western horizon. ...	Setting. ...	Evening. ...	True or cosmic.	Sun setting.
			Apparent or heliacal.	Sun set, and depressed below horizon sufficiently to enable the star to be seen.
		Morning. ...	True or achronic.	Sun rising.
			Apparent or heliacal.	Sun not yet risen, but depressed below horizon sufficiently to enable the star to be seen.

It is Ideler's opinion that, in Ptolemy's time, in the case of stars of the first magnitude, for heliacal risings and settings, if the star and sun were on the same horizon a depression of 11° was taken; if on opposite horizons a depression of 7°. For stars of the second magnitude, these values were 14° and 8½.° But if temples were employed as I have suggested, even cosmic and achronic risings and settings could be observed in the case of the brightest stars.

Before we begin to consider the question of stars at all, we must be able to describe them, to speak of them in a way that shall define exactly what star is meant. We can in these days define a star according to its constellation or its equatorial or ecliptic co-ordinates, but all these means of reference were unknown to the earliest observers; still we may assume that the Egyptians could define some of the stars in some fashion, and it is evident that we here approach a matter of the very highest importance for our subject.

So far, as we have been dealing with the sun and the observations of the sun at rising and setting, we have taken for granted that the amplitude of the sun at the solstices does not change; the amplitude of 26° at Thebes, for the solstices, is practically invariable for a thousand years; but one of the results of astronomical work is that the *stars* are known to behave quite differently. In consequence of what is called precession the stars change their place with regard to the pole of the heavens, and further, in consequence of this movement, the position of the sun among the stars at the solstices and equinoxes changes also.

In the last lecture we considered what were called the ecliptic and the equatorial co-ordinates. The ecliptic was the plane in which the earth moves round the sun, and 90° from that plane we had the pole of the heavens; celestial latitude we found reckoned from the plane of the ecliptic north and south up to the pole of the heavens, and celestial longitude we reckoned along the plane of the ecliptic from the first point of Aries. We had also declination reckoned from the equator of the earth prolonged to the stars, and right ascension reckoned along the equator from the first point of Aries. The pole of the heavens then we must regard as fixed, but the pole of the earth is not fixed, but slowly moves round it. *In consequence of that movement there is a change of declination in a star's place.*

Going back to the tables, we find that the amplitude of a body rising or setting at Thebes or anywhere else depends upon its declination, so that if from any cause the declination of a star changes, its amplitude must change at any particular place.

That is the first point where we meet with difficulty, because if the amplitude changes it is the same as saying that the place of star rising or star setting changes; that is, a star which rose in the east in a certain amplitude this year will change its amplitude at some future time.

The real cause of the precession of the stars lies in the fact that the earth is not a sphere, its equatorial diameter being longer than its polar diameter, so that there is a mass of matter round the equator in excess of what we should get if the earth were spherical. Suppose that matter to be represented by a ring. The ring is differently presented to the sun, one part being nearer than the other, the nearer part being attracted more forcibly. If we take the point where there is the greatest attraction, and draw a line to the least, we can show that the case stands in this way: that the sun's pull may be analyzed into two forces, one of them between the sun and the point in a direction parallel to the line joining the centre of the sun and the centre of the ring, and another force at right angles to it. The question is, what will that force at right angles do?

---

[1] Continued from p. 60.

[1] Biot, "Traité élémentaire d'Astronomie physique," 3rd edition, vol. iv. p. 625.

Here we have a model showing the rotation of the earth on its axis, and the concurrent revolution of the sun round the earth once a year. To represent the downward pull it is perfectly fair if I add a weight. Then the earth's axis, instead of retaining its direction to the same point as it did before, is now describing a circle round the pole of the heavens. It is now a recognized principle that there is, so to speak, a wobble of the earth's axis round the pole of the heavens in consequence of the attraction of the sun on the nearer point of this equatorial ring being greater than on the part of the equatorial ring removed from it. That precession movement is not quite so simple as it is shown by this model, because what the sun does in this way is done to a very much larger extent by the moon, the moon being so very much nearer to us.

In consequence, then, of this luni-solar precession we have a variation of the points of intersection of the planes of the earth's equator and of the ecliptic; in consequence of that we have a difference in the constellations in which the sun is at the time of the solstices and at the equinoxes; and, still more important, we have another difference, viz. that the declinations, and therefore the amplitudes, and therefore the places of setting and rising of the stars, change from century to century.

Having thus become acquainted with the physical cause of that movement of the earth's axis which gives rise to what is called the precession of the equinoxes, we have next to inquire into some of the results of the movement. The change of direction of the axis in space has a cycle of something between 25,000 and 26,000 years. As it is a question of the change of the position of the celestial equator, or rather of the pole of the celestial equator, amongst the stars in relation to the pole of the heavens, of course the declinations of stars will be changed to a very considerable extent; indeed, we easily see that the declination of a star can vary by twice the amount of the obliquity, or 47°, so that a star at one time may have zero declination—that is, it may lie on the equator—and at another it may have a declination of 47° N. or S. Or, again, a star may be the pole star at one particular time, and at another it will be distant from the pole no less than 47°. Although we get this enormous change in one equatorial co-ordinate, there would from this cause alone be practically no change with regard to the corresponding ecliptic co-ordinate—that is to say, the position of the star with reference to the earth's movement round the sun. This movement takes place quite independently of the direction of the axis, so that while we get this tremendous swirl in declination, the latitudes of the stars or their distance from the ecliptic north or south will scarcely change at all.

Among the most important results of these movements dependent upon precession we have the various changes in the pole star from period to period, due to the various positions occupied by the pole of the earth's equator. We thus see how in this period of 25,000 years or thereabouts the pole stars will change, for a pole star is merely the star near the pole of the equator for the time being. At present, as we all know, the pole star is in the constellation Ursa Minor. During the last 25,000 years the pole stars have been those lying nearest to a circle struck from the pole of the heavens with a radius of 23½°, which is equal to the obliquity of the ecliptic; so that about 10,000 or 12,000 years ago the pole star was no longer the little star in Ursa Minor that we all know, but the big star Vega in the constellation Lyra. Of course 25,000 years ago the pole star was practically the same as it is at present.

Associated with this change of the pole star there is another matter of the highest importance to be considered, because as the axis is being drawn round in this way, the point of intersection of the two fundamental planes, the plane of the earth's rotation and the plane of the earth's revolution, will be liable to change, and the period will be the same, about 25,000 years. Where these two planes cut each other we have the equinoxes, because the intersection of the planes defines for us the vernal and the autumnal equinoxes; when the sun is highest and lowest between these points we have the solstices. In a period of 25,000 years the star which is nearest to the equinox will return to it, and that which is nearest the solstice will return to it. During the period there will be a constant change of stars marking the equinoxes and the solstices.

The chief points in the sun's yearly path then will change among the stars in consequence of this precession. It is perfectly clear that if we have a means of calculating back the old positions of stars, and if we have any very old observations, we can help matters very much, because the old observations—if they were accurately made—would tell us that such and such a star rose with the sun at the solstice or at the equinox at some special point of ancient time. If it be possible to calculate the time at which that star occupied that position with regard to the sun, we have an astronomical means of determining the time, within a few years, at which that particular observation was made.

Very fortunately we have such a means of calculation, and it has been employed very extensively at different periods, chiefly by M. Biot in France, and quite recently by German astronomers, in calculating the positions of the stars from the present time to a period of 2000 years B.C. We can thus determine with a very high degree of accuracy, the latitude, longitude, right ascension, declination, and the relation of the stars to an equinox, a solstice, or a pole, as far back as 2000 years B.C. Since we have the planes of the equator and ecliptic cutting each other at different points in consequence of the cause which I have pointed out—the attraction of the sun and moon—we have a fixed equator and a variable equator depending upon that. In consequence of the attraction of the planets upon the earth, the plane of the ecliptic itself is not fixed, so that we have not only a variable equator but also a variable ecliptic. What has been done in these calculations is to determine the relations and the results of these variations.

A simpler, though not so accurate a method, consists in the use of the precessional globe, one of which I have here. In this we have two fixed points at the part of the globe representing the poles of the heavens, on which the globe may be rotated; when this is done the stars move absolutely without any reference to the earth or to the plane of the equator, but purely with reference to the ecliptic. We have, then, this globe quite independent of the earth's axis. How can we make it dependent upon the earth's axis? We have two brass circles at a distance of 23½° from each pole of the heavens (north and south), these represent the circle described by the pole of the earth in the period of 26,000 years. In these circles are 24 holes in which I can fix two additional clamping screws, and rotate the globe with respect to them by throwing out of gear the two points which produced the ecliptic revolution. If I use that part of the brass circle which is occupied by our present pole star, we get the apparent rotation of the heavens with the earth's axis pointing to the present pole star.

If we wish to investigate the position of things, say 8000 years ago, we bring the globe back again to its bearings, and then adjust the screws into the holes in the brass circles which are proper for that period. When we have the globe arranged to 6000 years B.C. (*i.e.* 8000 years ago), in order to determine the equator at that time all we have to do is to paint a line on the globe in some water-colour, by holding a camel's hair pencil at the east or west point. That line represents the equator 8000 years ago. Having that line, of course the intersection of the equator with the ecliptic will give us the equinoxes, so that we may affix a wafer to represent the vernal equinox. Or if we take that part of the ecliptic which is nearest to the north pole and therefore the declination of which is greatest, viz. 23½° N., we have there the position of the sun at the summer solstice, and 23½° S. will give us the position of the sun at the winter solstice. So by means of such a globe as this it is quite possible to determine the position of the equator among the stars, and note those four important points in the solar year, the two equinoxes and the two solstices. I have taken a period of 8000 years, but I might just as easily have taken a greater or a smaller number. By means of this arrangement, therefore, we can determine within a very small degree of error without any laborious calculations, the distance of any body north or south of the equator, *i.e.* its declination.

The positions thus found, say, for intervals of 1000 years, may be plotted on a curve, so that we can, with a considerable amount of accuracy, obtain the star's place for any year. Thus the globe may be made to tell us that in the year 1000 A.D. the declination of Fomalhaut was 35° S., in 1000 B.C. it was 42°, in 2000 it was about 44°, in 4000 it was a little over 42° again, but in 6000 B.C. it had got up to about 33°, and in 8000 B.C. to about 22°.

The curve of Capella falls from 41° N. at 0 A.D., to 10° at 6000 B.C., so we have in these 6000 years in the case of this star run through a large part of that variation to which I drew your attention.

Here is the curve of Sirius. This star, in 0 A.D., had a declination of 24° S.; but 5000 years B.C. it had a declination of something like 31½°. In Sirius we have the curve plotted from the computations of Mr. Hind, who has kindly placed them at my disposal. From other computations supplied by him, I have ascertained that the globe is a very good guide indeed within something like 1° of declination, always assuming that the star has no great proper motion. Considering the difficulty of the determination of amplitudes in the case of buildings, it is clear that the globe may be utilized with advantage, at all events in the first instance.

Now that we are familiar with the effect of the precession of the equinoxes in changing the amplitudes of the rising and setting places of stars, we can return to the consideration of the temples. So far, we have considered those built in relation to the sun, in the case of which body there is, of course, no precessional movement, so that a temple once oriented to the sun would remain so for a long time. After some thousands of years, however, the change in the obliquity of the ecliptic would produce a small change in the amplitude of a solstice.

Suppose we take, as before, that region of the earth's surface in the Nile valley with a latitude of about 26° N. The temples there built to observe the sun will have an east and west aspect true if they have anything to do with the sun at the equinoxes, and will have an amplitude of about 26° N. or S. if they have anything to do with the sun at the solstices.

The archæologists who have endeavoured to investigate the orientations of these buildings have found that they practically face in all directions; the statement is that their arrangement is principally characterized by the want of it; they have been put down higgledy-piggledy; there has been a symmetrophobia, mitigated by a general desire that the temple should face the Nile. This view may be the true one, if stars were not observed as well as the sun; for at Thebes, if any temple have an amplitude more than 26° N. or S. of E. or W., it cannot by any possibility have been used, as we have seen the temples at Karnak might have been used, for observations of the sun; for since the maximum declination of the sun is almost 24½° (it is at present only 23½°), represented by an amplitude of 27°, no temple oriented in a direction more northerly or more southerly could get the light of the sun along its axis.

Let us see, then, if the builders of them had any idea in their minds connected with astronomy. If they had, we may conclude that there was some purpose of utility to be served, as the solar temples were used undoubtedly, among other things, for determining the exact length of the solar year. When we come to examine these non-solar temples, the first question is, Do they resemble in construction the solar ones? Are the horizontal telescope conditions retained? The evidence on this point is overwhelming. Take the temple of Denderah. It points very far away from the sun; the sun's light could never have enfiladed it. In many others pointing well to the north or south, the axis extends from the exterior pylon to the Sanctuary or Naos which is found always at the closed end of the temple. We have the same number of pylons, gradually getting narrower and narrower as we get to the Naos, and in some there is a gradual rise from the first exterior pylon to the part which represents the section of the Naos, so that a beam of horizontal light coming through the central door might enter it over the heads of the people flocking into the temple, and pass uninterruptedly into the Sanctuary.

In these, as at Karnak, you see we have this collimating axis. We have the other end of the temple blocked; we have these various diaphragms or pylons, so that, practically, there is absolutely no question of principle of construction involved in this temple that was not involved in the great solar temple at Karnak itself.

We made out that in the case of the temples devoted to sun-worship, and to the determination of the length of the year, there was very good reason why all these attempts should be made to cut off the light, by all these diaphragms and stone ceilings, because, among other things, one wanted to find the precise point occupied by the sunbeam on the two or three days near the winter and summer solstices in order to determine the exact moment of the solstice.

But if a temple is not intended to observe the sun, why these diaphragms? Why keep the astronomer, or the priest, so much in the dark? There is a very good reason indeed; because the truer the orientation of the temple to the star, and the greater the darkness he was kept in, the sooner would he catch the rising star. In the first place, the diaphragms would indicate the true line that he had to watch; he would not have to *search* for the star which he expected; and obviously the more he was kept in the dark the sooner could he see the star.

The next point that I have to make is that in the case of some of these temples which are not directed to the sun we get exactly the same amplitudes in different localities. To show this clearly it will be convenient to bring together the chief temples near Karnak and those having the same amplitudes elsewhere.

We can do this by laying down along a circle the different amplitudes to which these various temples point. To begin with, I will draw your attention to those temples which we have already discussed with an amplitude of 27° or 26°, at Abydos, Thebes, and Karnak. Next we have non-solar amplitudes at Karnak and Thebes, associated with temples having the same amplitude at Denderah, Abydos, and other places. We have the majority of the non-solar temples removed just as far as they can be in amplitude from the solar ones, for the reason that they are as nearly as possible *at right angles* to them. We have temples with the same amplitudes high north and high south, in different places—temples, therefore, which could not have been built with reference to the sun; just as we have at different places temples with the same amplitudes which *could* have been used for solar purposes.

In connection with the possible astronomical uses of these temples, I find that when one of these temples has been built, the horizon has always been very carefully left open; there has always been a possibility of vision along the collimating axis prolonged. Lines of sphinxes have been broken to ensure this; at Medinet Abou, on the opposite side of the river to Karnak, we have outside this great temple a model of a Syrian fort. If we prolong the line of the temple from the middle of the Naos through the systems of pylons, we find that in the model of the fort an opening was left, so that the vision from the Sanctuary of the temple was left absolutely free to command the horizon.

It may be said that that cannot be true of Karnak, because we see on the general plan that one of the temples, with an azimuth of 71° N., had its collimating axis blocked by numerous buildings. That is true; but when one comes to examine into the date of these buildings, it is found that they are all very late; whereas there is evidence that the temple was one of the first, if not the very first, of the temples built at Thebes.

Mariette spent a long time in examining the temple of Karnak. His idea is that the part of the temple near the Sanctuary represents the first part of the building; and at that time the great temple of Karnak—enormous though it is now—was so small and entirely out of the way of the line of the axis of the temple of Maut that its existence might have been entirely neglected. There was first a square court like the court of the Tabernacle, and very shortly after that a very laboured system of pylons was introduced to restrict the light. The next stage shows the Sanctuary thrown back away from the court; then, after that, more complication is introduced by the addition of pylons, until finally, after two or three extensions, the length of the temple was quadrupled. So that the proof is positive that at first the horizon of the temple of Maut was left perfectly clear. Why it was subsequently blocked I shall suggest afterwards.

The next point to be noticed is that there is in very many cases a rectangular arrangement, so that if the sun were observed in one temple and a star in the other, there would be a difference of 90° between the position of the sun and the position of the star at that moment. This would, of course, apply also to two stars. Sometimes this rectangular arrangement is in the same temple, as at Karnak, sometimes in an adjacent one, as at Denderah.

If we look at Denderah we find that we have there a large temple inclosed in a square *temenos* wall, the sides of which are parallel to the sides of the temple; and also a little temple at right angles to the principal one.

It is hardly fair to say that a rectangular arrangement, repeated in different localities, is accidental; it is one which is used to some extent in our modern observatories.

The perpetual recurrence of these rectangular temples shows, I think, that in all the pairs of temples which are thus represented, there was some definite view in the minds of those who built them.

Another point is that, when we get some temples pointing a certain number of degrees south of east, we get other temples pointing the same number of degrees south of west, so that some temples may have been used to observe risings and others settings of stars in the same declination. It is then natural of course to conclude that these temples were arranged to observe the rising and setting of the same stars.

J. Norman Lockyer.

(*To be continued.*)

BOTANICAL ENTERPRISE IN THE WEST INDIES.

We have several times had occasion to mention the mission of Mr. D. Morris, the Assistant Director of the Royal Gardens, Kew, to the West Indies, in connection with the extension and organization of botanical stations in the British colonies of that region; and the *Kew Bulletin* for May and June, as we have already noted, contains his report thereon. It is a lengthy and interesting document, from which we propose to extract some particulars that may be welcome to our readers, and serve to put on record the reviving enterprise in the development of the natural resources of that part of the Empire. The primary object of Mr. Morris's visit was to settle the practical details of a scheme for establishing and administering a number of smaller botanical gardens in connection with the larger gardens of Trinidad and Jamaica. The main purpose of these gardens is to raise plants of economic value, suitable for cultivation in the various islands, "and to do all that is possible to encourage a diversified system of cultural industries, and thus relieve the planters from the results inevitable from the fluctuations of prices in the one or two staples to which they have hitherto confined their attention"; but they will also be made, as far as possible, pleasant places of public resort. Mr. Morris met with a hearty reception everywhere, and great interest was manifested in the work by the negro freeholders, in some of the islands, as well as the English colonists. The men in charge of these experimental stations, as they may be called, rather than botanical gardens, are mostly trained men from Kew; and Kew is the centre from which plants and seeds of economic plants likely to succeed in the West Indies are distributed. Mr. Morris left Kew in November last, and returned home at the end of February. Advantage was taken of his outward journey to send by the same ship, under his immediate supervision, a number of Wardian cases filled with Gambier plants. Gambier, it may be added, is the name of a substance used in tanning, obtained from *Uncaria Gambier*, Roxb.; and the plants had been raised at Kew from seeds received from the Straits Settlements, several attempts to introduce plants from the East having failed. How the plants were successfully carried to the West Indies we learn from the following passage in the report:—

"Owing to the cold weather, the cases containing the plants on board the *Atrato* were placed below in the main saloon. There was very little direct light in the daytime, but the question of warmth was for the moment of more importance than that of light. It was also hoped that they could be placed on deck in a day or two at the most. The weather during the whole of the first week, however, continued very cold, and it was impossible to expose the plants on deck. Under these circumstances it was fortunate that the electric light, with which every part of the ship was supplied, was available to try an experiment of some interest. Although the plants received very little light during the day, they had a good supply of the electric light during the night, and the plants in the cases more fully exposed to the electric light were afterwards found to be in a much better condition than the others. It is well known that plants will thrive under the influence of artificial light, but in this instance there was so little direct light available during the day, that the plants had to depend almost entirely on the light they received at night. The Gambier plants are particularly sensitive as regards a diminution of light. During the prevalence of fogs at Kew they have been known to drop their leaves within a day or two, and to remain bare during the rest of the winter. This may have been, in some measure, also due to the injurious influence of the fog itself.

"The use of electric light for the safe transit of such valuable plants as are obliged to be despatched from this country during the winter months is evidently capable of being greatly extended. It may also be utilized in the case of tropical plants arriving in this country from abroad, during the prevalence of cold weather. Such plants could be placed below directly the weather is becoming too cold for them on deck, and then the more electric light they have the better."

Out of the whole consignment to the various islands only ten plants succumbed; but this was due to an oversight in carrying the case on to Trinidad and La Guayra, and having to bring it back again to St. Vincent, thereby causing a delay in landing of ten days.

Mr. Morris visited successively Antigua, Dominica, Montserrat, St. Kitts, Anguilla, Tortola, Santa Lucia, St. Vincent, Grenada, Barbados, and Jamaica, being present at the opening of the Exhibition at the last-named island. Everywhere the Governors and other officials seem to have done their utmost, both personally and indirectly, to assist Mr. Morris in fulfilling the object of his mission. Established gardens were inspected, sites for new gardens selected, means discussed, and addresses delivered, from which it is confidently hoped that substantial advantages to the cultural industries may accrue.

Mr. Morris's Report, which may be obtained for the sum of fourpence, is a valuable and interesting account of the present condition and future prospects of planting in the various islands, and should be in the hands of all concerned. We conclude this notice with an extract from a description of the lime plantations in Montserrat, "where the immense golden heaps of ripe fruit were alone worth a journey to the West Indies."

"The West Indian lime (*Citrus medica*, var. *acida*) appears to be a thin-skinned local variety, little known outside the West India Islands. It yields juice of a singularly pure acid flavour, and it deserves to be much better known in this country in the fresh state for making 'lemon' beverages, as well as for general use in cookery. The enterprise of the Montserrat Company extends to other things besides limes. Nevertheless, from limes alone it is possible to produce a variety of articles more or less valuable. The limes themselves are exported as gathered, or they are preserved in salt water, and shipped in a pickled state for consumption in certain parts of the United States. Lime-juice, obtained by compression, is exported either raw or in a concentrated state. This latter is obtained by evaporating the raw juice in boilers until it is reduced to about one-twelfth of the original bulk, when it is ready for export as a dark, viscid substance like molasses. This is used for the preparation of commercial citric acid. From the rind of the fruit, by a process known as 'ecuelling,' which consists of gently rubbing the fruit on rounded projections arranged inside a brass basin, a very fine essence of limes is obtained. Again, by distilling the raw lime-juice a spirit is obtained known as oil of limes."

NOTES.

THE deputation which is to submit to Sir Michael Hicks Beach to-morrow a statement of the facts relating to the proposed British Institute of Preventive Medicine, will be large, influential, and thoroughly representative of the various departments of science. It is expected that the following gentlemen will speak: Sir Joseph Lister, the Duke of Westminster, Sir Henry Roscoe, Prof. Dewar, Mr. Haldane, M.P., Q.C., and Prof. Ray Lankester. A letter from Prof. Huxley will be read.

THE list of those selected for Birthday Honours includes Dr. Archibald Geikie, on whom the honour of knighthood has been conferred, and Mr. Robert Giffen, who has been made C.B.

IN the course of an investigation, part of which has already been communicated to the Royal Society, Prof. Roberts-Austen has discovered the most brilliantly coloured alloy as yet known. It has a rich purple colour, and bright ruby tints are obtained when light is reflected from one surface of the alloy to another. It contains about 78 per cent. of gold, the rest of the alloy being aluminium. The constants of the aluminium-gold series of alloys are now being examined, and will shortly be published.

ON Tuesday last, at Oxford, Convocation sanctioned the expenditure of very considerable sums of money in order to provide increased accommodation for the medical and science schools. The Lecturer in Human Anatomy, Mr. Arthur Thomson, estimated that the immediate wants of his department necessitated the expenditure of £7000. With this sum might be provided a laboratory, which would include dissecting-rooms, a museum, working rooms, and a lecture theatre. Hitherto the accommodation provided for the lecturer has been of a temporary character, and has now proved itself utterly inadequate for the requirements of his class. The number of students now studying in Oxford with the intention of passing the M.B. examination is 67. As illustrating the growth of the class, and the interest taken in this school, it may be mentioned that in 1885 the lecturer's class consisted of only three members. The Deputy Professor of Physiology (Dr. Ray Lankester) required the more modest sum of £2000 in order to supply the deficiencies in the department of Morphology. With this sum two laboratories could be provided, one 40 × 20 feet, and the other 30 × 20 feet. Meanwhile the departments of Ethnology and Geology find themselves cramped for space at the University Museum, and Convocation has granted the sum of £1300 to provide rooms for the use of the Curator and the servants of the Museum, and increased accommodation for teaching. The Hope Professor of Zoology (Prof. Westwood) needed only the expenditure of £350 upon additions and improvements in his department at the University Museum. The expenditure of these various sums, amounting in the aggregate to nearly £11,000, will place the School of Medicine and the related sciences in a satisfactory position, and the University of Oxford is to be congratulated on its appreciation of the importance of these departments, and the liberality with which it maintains them.

THE Gold Medal of the Linnean Society has this year been awarded to Dr. Edouard Bornet, of Paris, for distinguished researches in botany. His earliest publications related to the structure and life-history of Fungi and Lichens, but his name is best known for the important researches in which, with his friend M. Thuret, he has been for some years engaged, on the life-histories of Algæ, and for his valuable contributions on this subject in the "Études Phycologiques," and the "Notes Algologiques," with their beautiful illustrations.

AT a meeting of the Ashmolean Society, Oxford, on June 1, there was an interesting discussion on a paper, by Mr. Romanes, on Weismann's theories of heredity, in which Prof. Lankester and Mr. Poulton took prominent parts.

M. DOULIOT, Demonstrator in Botany at the Museum of Natural History, Paris, has undertaken a scientific expedition to Madagascar.

MR. NORMAN LOCKYER, F.R.S., has undertaken to give a lecture at Bedford College (for Ladies), Baker Street, on Wednesday next, at 4 o'clock, "On Natural Philosophy for Artists."

WE regret to have to record the death of Sir John Hawkshaw, F.R.S. He died on Tuesday last at his town residence, Belgrave Mansions, in his 81st year. The greatest of his many engineering feats was the construction of the Severn Tunnel. He was President of the Institution of Civil Engineers in 1862–63, and of the British Association at its Bristol meeting in 1875. He received the honour of knighthood in 1873.

SEVEN years have elapsed since the first International Ornithological Congress took place in Vienna, under the presidency of the late Crown Prince Rudolph. England was on that occasion, as a correspondent wrote at the time, "conspicuous by her absence," and at the second Congress, which has just been held at Budapest, Great Britain was but feebly represented. It is difficult to understand this unwillingness of Englishmen to visit an International Congress. Our countrymen are always sure of a hospitable reception, the interchange of ideas with foreign colleagues is pleasant and profitable, the personal friendships which result are of permanent value, and in the case of Museum officials the relations established with the Museums of the Continent invariably result in mutual benefit. The great question which all zoologists can discuss is that of nomenclature. This year a preliminary skirmish took place at Frankfort, where the annual meeting of the German Ornithological Society was held on May 11 and 12, under the presidency of Prof. Wilhelm Blasius, of Brunswick. The Senckenburg Museum at Frankfort had been closed for four years, and had been opened to the public only four days before the arrival of the visitors. Prof. Noll, the well-known editor of the *Zoologischer Garten*, welcomed the German Ornithological Society in a few well-chosen words, and then followed the discussion on zoological nomenclature, which occupied the best part of two days of hard work. The proposals of the Committee appointed to examine into and report on the rules of zoological nomenclature were fully discussed, and were adopted, though, by the courtesy of the members, Mr. Bowdler Sharpe, and Mr. Büttikofer, of the Leyden Museum, were allowed to state their objections to some of the propositions. The members and guests of the Society were conducted round the Museum by Prof. Noll and Dr. Hartert, and great satisfaction was expressed at the excellent condition in which Prof. Rüppell's types were found to be. The ornithological collection has been carefully catalogued by Dr. Hartert, and his recently-published catalogue of the collection is an admirable piece of work. At the conclusion of the meeting, an adjournment took place to the Zoological Gardens, where the visitors were hospitably entertained by the Director, who personally conducted them round the Gardens. From Frankfort a detachment of members and guests proceeded to Vienna and thence to Budapest, to attend the meeting of the Ornithological Congress.

MESSRS. MACMILLAN have nearly ready for publication "A History of Human Marriage," by Dr. Edward Westermarck, Lecturer on Sociology at the University of Finland, Helsingfors. In an introductory note the work is commended to the attention of students by Dr. A. R. Wallace, who expresses a high opinion of the learning and insight displayed by the author. Dr. Westermarck differs widely in many respects from the opinions hitherto held by most anthropologists as to the development of the various forms of marriage.

IN the House of Commons on Friday last, there was an interesting debate on the Ordnance Survey. Mr. Roby, who introduced the subject, had much to say as to the unsatisfactory rate at which the Survey is proceeding, and Sir George Campbell effectively contrasted the work done in England with that done in other countries. In India, he said, the surveys were incomparably ahead of those in the United Kingdom; he was often surprised at the perfection of the surveys even of those portions of that vast country only reached by sportsmen or explorers. "In his own country he found nothing of the kind. There, in one of the most cultivated and civilized places in the world, they had nothing but the old survey. It was a disgrace to the country that we should not have decent maps." Mr. Chaplin, under whose department the Ordnance Survey has been placed, said what he could in defence of existing arrangements, but was not disposed to deny that there was much solid ground for complaint. He promised that his influence should be used to secure reform in various directions.

THE University College Biological Society has arranged for an excursion to Sheerness on Saturday, June 6. The excursion will leave Victoria at 10 a.m., and the time at Sheerness will be spent either in dredging or shore work. The party will be accompanied by Prof. Weldon.

THE Eastern papers report that an expedition has, by order of the Straits Government, commenced work on the frontier between Burmah and the Malay Peninsula. Its operations will be chiefly confined to Pahang. It is placed under the charge of Mr. Ridley, Director of Gardens and Forests in the Straits Settlements, accompanied by Mr. William Davison, Curator of the Raffles Library, Singapore, and Lieutenant Kelsall, R.A. The funds available for the expedition are 2000 dollars voted from the Straits Treasury. The object is to ascend the highest mountain in Pahang, incidentally noting all that can be learned about the physical features and the flora and fauna of the country. The expedition was to go by steamer to Pekan; thence up stream to Kuala Lipis; thence northerly up the Tembelinis and Sat rivers. Having ascended the latter river so far as it may be navigable for small canoes, the expedition will strike through forest and jungle, estimated to extend for sixty miles, till they emerge at Gunong Tahan, which is said to be about 8000 feet high. Ascending this mountain, and crossing what is called Cameron's plateau, they will then ascend Gunong Siam, a mountain the height of which has been estimated to be as much as 14,000 feet. Having completed this ascent, they will return by the same route, the estimated period of absence from Singapore being between two and three months. The party were to take with them three Tamil hunters and collectors attached to Mr. Davison's Museum staff, and three Malays of the Gardens and Forests Department.

AT the meeting of the French Meteorological Society on May 5, a discussion by M. Millot of fifty years' observations at Nancy was presented. The temperature and rainfall values were divided into two periods, viz. 1841–79 and 1880–90. These averages showed that the mean temperature had considerably decreased since the winter of 1879–80, and that the amount of rainfall had increased; the climate showed a tendency to become more continental. M. Teisserenc de Bort communicated the results of his inquiries respecting a destructive tornado which visited the town of Dreux on August 18 last. At 10h. 5m. p.m., Paris time, a sharp clap of thunder occurred, followed by heavy rain and hail for about a minute, and five minutes later the tornado broke over the town with a noise resembling that of an express train, making a furrow in the ground, and in less than a minute tiles were flying about, trees uprooted, and several houses destroyed. After a short course the effects of the tornado ceased, and it appeared to rise to the upper strata of air, but descended again with equal violence near Epone about 60 kilometres distant, the rate of translation being about 29 miles an hour. The action of the electricity seemed to be of an unusual nature; although much damage was done by it, no metallic object was fused, but only traces of fusion could be found in bad conducting bodies. Among other incidents an iron bedstead was dismounted, without trace of fusion. The paper was illustrated by several photographs, showing the damage done in various parts of the path.

DR. J. HANN has communicated another important treatise to the Vienna Academy, entitled "Studies on the Conditions of Air-pressure and Temperature on the Summit of the Sonnblick, with remarks upon their importance for the theory of cyclones and anticyclones." The work is based upon four years' observations, and is divided into eight sections, viz.:—(1) An investigation of the general meteorological conditions under which the maxima and minima of air-pressure occur on the Sonnblick. The anomalies of pressure are more marked above than below, and are increased by the accompanying temperature anomaly, which is relatively high in barometric maxima, and relatively low in barometric minima. (2) The range of temperature during the passage of a barometric wave. This is, at least during the winter season, the opposite to that at the lower level. (3) Temperature with varying amount of cloud in winter. The highest temperature coincides with the least cloud, upon the summit, and conversely on the plain. The clear winter days on the Sonnblick have relatively high temperature with great dryness, and these conditions are characteristic of the barometric maxima. (4) Monthly maxima and minima of temperature. The former mostly occur during barometric maxima, and the latter when the high pressure lies in the west or north, and while a barometric minimum exists over Italy or the Adriatic. (5) Temperature and air-pressure on the Sonnblick during barometric minima over Central Europe, especially over the Eastern Alps. The mean temperature at the height of 6650 feet during the passage of barometric minima was below the normal, amounting on an average to 2°·5 F. during the winter season. The use of deviations of pressure and temperature in answering many questions of atmospheric physics is here discussed. (6) Vertical distribution of temperature, and mean temperature in a column of air of 3 kilometres in height. The calculations have been made separately for each winter. (7) Preliminary indications respecting the relations of the wind-directions to barometric maxima and minima. A considerable divergence (45°–90°) is shown from the directions as observed below, and the results confirm the conclusions drawn from cloud observations by J. A. Broun and others. (8) Refutation of some objections against the conclusiveness of temperature observations on mountain summits, and general remarks on cyclones and anticyclones. The author points out that recent mountain temperature observations and other facts are opposed to the explanation of barometric maxima and minima in extra-tropical regions by purely thermic considerations.

THE relations of weather and disease have been recently investigated by Herr Magelssen, of Leipzig, who, having formerly called attention to the nature of certain "waves" which recur in the variations of temperature (distinguishing waves of about 12 days, 50 days, and 18 to 20 years duration), now traces a connection of these with diseases and mortality. The year-waves especially show this connection; the mortality (in our latitudes) varying with the winter temperature. The least mortality (relatively) is at the middle part of the temperature periods. The injurious influence of heat is dominant in the more southern latitudes (such as Vienna), while cold begins to act beneficially. In northern places, mild winters prove injurious where several very mild winters come in succession (*e.g.* Stockholm in 1871–74). The most favourable conditions seem to be an alternation of moderately cold and moderately mild winters. Too much importance, the author thinks, has been attached to relative humidity. He further offers proof that infectious disease is even more dependent on weather than disease of the respiratory organs, or arising from chill.

THE value of systematic observation of snow is now being recognized in meteorology; and in Russia observations were commenced in January last year at 428 stations in the European portion of the Empire, 21 in the Asiatic, and 55 in the Caucasus. At first it was simply reported daily whether there was a continuous snow-covering about the station or not. But last winter the inquiry has been extended to the depth and general behaviour of the snow. Thus it is expected that in a few years, some valuable climatological material will have been accumulated at St. Petersburg. The report of Herr Berg on the snow in the early months of 1890, in European Russia (*Repert. für Meteor.*), contains a map showing the southern and western limit of the continuous snow-covering for the first and fifteenth of each of the months January to April. In the west the snow extended steadily till the beginning of March, the limit being then close to the Baltic. In the south-east, there was steady advance till February, and as far as the coast of the Caspian. In the south, the advance was fluctuating, there being a maximum in the middle of January, and the middle of February, both reaching to the Black Sea coast. The retirement of the snow-limit began in the south and south-east in the middle of February; in the west about half a month later. The general direction was north-east. On April 15 the limit passed through Onega on the White Sea, Wetluga, and Katherinenburg. By the first of May, all European Russia was free from snow. Herr Berg describes the weather accompanying the disappearance of the snow, and traces its causation.

A DIRECT observation of hail in the process of formation is recorded in the *Naturw. Rundschau*. In the afternoon of a squally day Prof. Tosetti, looking eastwards through the window of a house (in Northern Italy) which, with two others, enclosed a court, saw the rain which streamed down from the roof to the right, caught by a very cold wind from the north, and driven back and up in thick drops. Suddenly a south wind blew, and the drops, tossed about in all directions, were transformed into ice balls. When the south wind ceased, this transformation also ceased, but whenever the south wind recurred, the phenomenon was reproduced, and this was observed three or four times in ten minutes.

Engineering of the 29th ult. states that an extraordinary accident had occurred at the London-Paris Telephone Office in the Palais de la Bourse. One of the *employés*, a gentleman named Weller, wished to communicate with the London office on a matter of service. He had already rung up the English officials, and, the bell having sounded in reply, took up the receivers and put them to his ears, when he suddenly sustained a shock of electricity of such severity that it threw him staggering backwards against the door of the telephone cabinet, which, not having been properly fastened, flew open, with the result that he was thrown heavily to the ground. It appears from inquiries that similar accidents, although less serious, have occurred at this telephone office on several previous occasions. The officials attribute them to lightning striking the wire, either at San Gatte, where the submarine cable ends, or at the terminus of the land wire on the Palais de la Bourse. Such accidents, it is declared, might be easily prevented by the simple expedient of erecting lightning conductors at the point where the cable comes ashore, and at the terminus in Paris.

IN the nineteenth annual report of the directors of the Zoological Society of Philadelphia, attention is called to the unprecedented destruction of many of the more valuable and important animals of the native American fauna, and to the need for the immediate adoption of every means which can be employed to save them from complete extinction. The directors think that a good deal may be done in furtherance of this object, both in zoological gardens and private preserves. Of all the bisons now surviving outside the National Park, probably nine-tenths are comprised in a few herds owned by private individuals and zoological societies.

A FINE tortoise, weighing 87 pounds, obtained by the U.S. Fish Commission steamer *Albatross*, during her recent visit to the Galapagos Islands, has recently been deposited in the Zoological Park at Washington, D.C. The specimen was collected by Mr. C. H. Townsend on Duncan Island, and is of much interest, not only on account of the locality it represents, but as showing that Dr. Baur was a little hasty in deciding that *Testudo ephippium* is only a synonym of *T. abingdoni*. The Duncan Island tortoise agrees exactly with Dr. Günther's figure of *T. ephippium*, and is entirely distinct from the Abingdon Island species, which is also well-figured in Dr. Günther's paper. This figure shows a little emargination in the second marginal scute, which might seem accidental, but as it is exactly repeated in the specimen belonging to the U.S. National Museum, and as the emargination exists in the bony carapace, it is probably a constant specific character. Dr. Günther gives Indefatigable Island as the locality of *T. ephippium*, and if this be correct the species occurs on at least two islands of the group. Besides the Duncan Island Tortoise, examples of *T. vicina* and *T. nigrita* are now living in the Zoological Park, while the U.S. National Museum possesses skeletons of *T. abingdoni* (imperfect), *T. vicina*, and *T. nigrita*. The locality of this last-named species is still uncertain, but there is some reason to suppose that it may be from Chatham Island. *T. nigrita* has the most arched carapace of any species, *T. ephippium* and *T. abingdoni* the longest and anteriorly most compressed and elevated carapaces. Between these lie in the order named *T. microphyes* and *T. vicina*. There is a direct correlation between the anterior height of the carapace and the length of the neck, the rule being the higher the carapace the longer the neck, *T. nigrita* and *T. abingdoni* having respectively the shortest and longest necks. Mr. Townsend writes that tortoises are now extremely rare on Duncan Island.

THE June number of the *Zoologist* contains an interesting paper on the habits of the moose, by Mr. J. G. Lockhart. One of the points noted by the author is, that moose generally lie with the tail to windward, trusting to their senses of hearing and smelling, which are remarkably acute, to warn them of approaching danger from that quarter; they can use their eyes to warn them from danger to leeward, where hearing, and especially smelling, would be of little use. While they are sleeping or chewing the cud, their ears are in perpetual motion, one backward, the other forward, alternately. They also have the remarkable insight to make a short turn and sleep below the wind of their fresh track, so that anyone falling thereon and following it up is sure to be heard or smelt before he can get within shooting distance.

MR. L. UPCOTT GILL has published as a pamphlet a paper read by the Rev. H. A. Soames before the Bromley Naturalists' Society on the scientific measurement of children. Mr. Soames says he finds such measurements as he describes, taken every term, a good guide as to whether his pupils may be pressed with work or not. "If the increase is regular and the weight fair, according to the height, I do not fear to press them; but if, on the other hand, the weight is low, or if the height increases and not the weight, or if the increase in height is too rapid, I think it a very fair excuse for laziness, and take great care that too much work is not expected from them."

THE first volume of Sir William Thomson's "Popular Lectures and Addresses" (Macmillan), has reached a second edition. The third volume has also just been published, and the author hopes that the second volume may appear in the course of a year or two.

THE new number of the Journal of the Anthropological Institute (vol. xx., No. 4) opens with a paper in which Lady Welby calls attention to what she calls an apparent paradox in mental evolution. The number also includes a paper, by Mr. F. W. Rudler, on the source of the jade used for ancient implements in Europe and America; and the Presidential address delivered by Dr. Beddoe.

THE Botanical Society of Edinburgh has issued the eighteenth volume of its Transactions and Proceedings. Dr. Aitchison's "Notes on the Products of Western Afghanistan and of North-Eastern Persia," forming the first part of the volume, may be obtained separately.

Two new parts (62 and 63) of the elaborate dictionary of Chemistry included in the "Encyclopaedie der Wissenschaften" (Breslau: Eduard Trewendt) have appeared. The eighth part of the hand-book of Physics, in the same Encyclopædia, has also been published.

THE ninth edition of "Telegraphy," by W. H. Preece and J. Sivewright (Longmans), has been published. The edition is described as "almost a new book." No fewer than 24 figures have been altered and 44 excluded, and there are now 265 as compared with 194 in the last edition. The authors have aimed at "providing such a general introduction to the art and science of telegraphy as will enable the student to proceed to the study of more advanced works, and give to the operator an intelligible explanation of the apparatus with which he has to deal."

MESSRS. LONGMANS, GREEN, AND CO. are issuing the tenth edition of Quain's "Elements of Anatomy." It will appear in three volumes, and is being edited by Prof. E. A. Schäfer and Prof. G. D. Thane. The second part of the first volume—by Prof. Schäfer—has just been published. The subject is general anatomy or histology.

PART 32 of Cassell's "New Popular Educator" has been published. Besides illustrations in the text, it contains a coloured map of Switzerland.

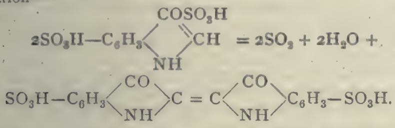
THE Geological Survey Department of Canada has issued the first of a series of descriptive and illustrated quarto memoirs on the Vertebrata of the Tertiary and Cretaceous rocks of the Canadian North-West Territory, prepared for the Survey by Prof. E. D. Cope, of Philadelphia. The Report is devoted exclusively to a consideration of the species from the Lower Miocene deposits of the Cypress Hills, in the district of Alberta, and consists of twenty-seven pages of letterpress, illustrated by fourteen full-page lithographic plates. The second part, which will contain illustrated descriptions of the Vertebrates of the Laramie formation of the North-West Territory, by the same author, is now in course of preparation.

MR. PERCY F. KENDALL has prepared a little volume entitled "Hints for the Guidance of Observers of Glacial Geology." It is intended to serve as an answer to the requests for guidance which have been made by members of the North-West of England Boulder Committee. The work is printed only on alternate pages, so that students using it will have space for occasional brief notes.

"AN approved Treatise of Hawks and Hawking by Edmund Bert," 1619, has just been reprinted, with an introduction by Mr. J. E. Harting. It is the rarest of English books on falconry, and no copy has come into the market for nearly twenty years. The reprint is as nearly a facsimile as it is possible to make it without the aid of photography, and a hundred copies only have been printed. It is issued by Mr. Quaritch.

INDIGOCARMINE, the commercially important disulphonic acid of indigo, has been synthesized in an extremely simple manner by Dr. Heymann in the laboratory of Messrs. Bayer and Co. of Elberfeld, and a description of the mode of operation is given in the new number of the *Berichte*. The reaction merely consists in acting with excess of fuming sulphuric acid upon phenyl glycocoll, C_6H_5—NH—CH_2—COOH, the aniline derivative of glycollic acid. When a quantity of fuming sulphuric acid is poured upon a tenth of its weight of phenyl glycocoll in a test tube, the phenyl glycocoll rapidly dissolves, the acid becoming coloured yellow and slightly elevated in temperature, while sulphur dioxide commences to be evolved. If the solution is then poured over ice the greenish-blue colour of indigocarmine is at once obtained. The best conditions for working the process on the large scale are as follows. One part of phenyl glycocoll is mixed with ten to twenty times its weight of fine sand so as to avoid local superheating during the process of addition to the fuming acid. The mixture is then introduced into about twenty times its weight of fuming sulphuric acid at a temperature of about 20°-25°. The fuming acid should contain at least 80 per cent. of sulphuric anhydride, and the temperature should be so controlled that it never exceeds 30° during the process of adding the mixture. The yellow solution thus obtained yields instantly the blue coloration due to indigocarmine on removing the large excess of sulphuric anhydride by the addition of ordinary oil of vitrol, sulphur dioxide being evolved. Upon further diluting with ice and addition of common salt (indigocarmine being more difficultly soluble in salt solutions than in pure water) the colouring-matter is precipitated, and may be readily isolated. The product thus obtained is found to consist of pure indigocarmine. The tints obtained with this product are vastly superior in beauty and clearness to those obtained with even the better kinds of commercial indigocarmine, on account of the higher degree of purity attained by this mode of preparation. The chemical changes occurring during the process appear to be as follows. The first product of the action of fuming sulphuric acid upon phenylglycocoll appears to be the sulphonic acid of indoxyl sulphate, 
$$\mathrm{SO_3H{-}C_6H_3}\Big\langle\begin{matrix}\mathrm{COSO_3H}\\ \\ \mathrm{NH}\end{matrix}\Big\rangle\mathrm{CH}.$$

This substance, however, is unstable, and decomposes upon the removal of the excess of SO_3 into indigo disulphonic acid, sulphur dioxide, and water, probably according to the following equation—



$$2\mathrm{SO_3H{-}C_6H_3}\Big\langle\begin{matrix}\mathrm{COSO_3H}\\ \\ \mathrm{NH}\end{matrix}\Big\rangle\mathrm{CH} = 2\mathrm{SO_2} + 2\mathrm{H_2O} +$$

$$\mathrm{SO_3H{-}C_6H_3}\Big\langle\begin{matrix}\mathrm{CO}\\ \mathrm{NH}\end{matrix}\Big\rangle\mathrm{C}=\mathrm{C}\Big\langle\begin{matrix}\mathrm{CO}\\ \mathrm{NH}\end{matrix}\Big\rangle\mathrm{C_6H_3{-}SO_3H}.$$

Of course the most important point of commercial interest about a new reaction is the yield, and in this respect Dr. Heymann is very fortunate, for already 60 per cent. of the theoretical has been attained. The process has consequently been patented by Messrs. Bayer and Co., and appears likely to become a very successful one.

THE additions to the Zoological Society's Gardens during the past week include a Water Buck (*Cobus ellipsiprymnus* ♀), a Leopard (*Felis pardus*), two Vulturine Guinea Fowls (*Numida vulturina*), two Mitred Guinea Fowls (*Numida mitrata*) from East Africa, presented by Mr. G. S. Mackenzie, F.Z.S.; a Peregrine Falcon (*Falco peregrinus*) from Scotland, presented by Mr. Thomas C. Smith; a Mountain Ka-Ka (*Nestor notabilis*) from New Zealand, presented by Mr. Herbert Furber; a Grey Squirrel (*Sciurus griseus*), a Squirrel (*Sciurus* sp. inc.) from North America, a Ducorp's Cockatoo (*Cacatua ducorpsi*) from the Solomon Islands, presented by Mr. Nicholas O'Reilly; two Ravens (*Corvus corax*) from Ireland, presented by Captain Ogilby; a Cheetah (*Cynælurus jubatus*) from Persia, three Blandford's Rats (*Mus blandfordi*), two —— Terrapins (*Clemmys* sp. inc.) from India, deposited; two Coypus (*Myopotamus coypus*) from South America, two Andaman Starlings (*Sturnia andamanensis*) from the Andaman Islands, two Red-billed Hornbills (*Toccus erythrorhynchus*), two African White Spoonbills (*Platalea alba*) from Africa, two Virginian Eagle Owls (*Bubo virginianus*) from North America, purchased; a Red Deer (*Cervus elaphus* ♂), a Japanese Deer (*Cervus sika* ♀), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE MERIDIAN PHOTOMETER.—In vol. xxiii. of the *Annals of the Harvard College Observatory*, Prof. E. C. Pickering and O. C. Wendell give and discuss the observations made at Cambridge, U.S., with the meridian photometer during the years 1882-88. The observations relate principally to stars north of the declination −40°. Vol. xiv. of the *Annals* contained the results of observations of the brightness of stars made with a small meridian photometer. The present volume deals with the photometric measurements of somewhat fainter stars, made by means of a similar but larger instrument.

REPORT OF HARVARD COLLEGE OBSERVATORY.—Prof. Pickering has just issued his Report for last year. He again urges the necessity of a fire-proof building for storing the 27,000 photographic plates of spectra, 9000 of which were taken in 1890. Legacies for the endowment of science in America are so common that it is not surprising to learn that the Observatory has received a gift of 25,000 dollars through the late Mr. J. I. Bowditch. During the past year 1309 photographs of stellar spectra have been taken with the Bache telescope at the station near Closica, in Peru. Nearly all of them relate to the region south of −20°. Mrs. Draper has added another instrument of the same kind to the Henry Draper Memorial. This is mounted in the Observatory grounds at Cambridge, and since September 1889, 2157 photographs have been taken with it, covering the sky north of −20°. By placing a prism of small angle over the objective, the spectra of stars as faint as the tenth magnitude have been obtained. Six stars with Type IV. spectra have been discovered. Spectra of fifteen planetary nebulæ have been photographed. The hydrogen line F has been shown to be bright in eight stars. Bright line stars of the Wolf-Rayet type now number twenty-eight, three having been added to the list during the past year. The names are given of thirty variable stars of long period, in which the hydrogen lines are bright at maximum. This peculiarity has furnished a means of discovering seven new variable stars. The 11-inch telescope has been used for a detailed study of the spectra of the brightest stars, with the result that β Aurigæ and ζ Ursæ Majoris have been discovered to be close binaries. One photograph of σ Herculis seems to show that this star also is double, but this has not been confirmed. With the 12-inch telescope a number of "canals" on Mars have been recognized, but only one of them was distinctly seen to be double. An important accession to the white spot surrounding the southern pole was found by photographs to have occurred between the nights of April 9 and 10. The Report concludes with a list of the numerous publications issued by the Observatory during the year.

THE SOLAR PARALLAX AND ITS RELATED CONSTANTS.

IT would be difficult to conceive a more masterly and comprehensive exposition of astronomical and physical constants than one just issued by Prof. W. Harkness, of the United States Naval Observatory. As is rightly pointed out, "The solar parallax is not an independent constant. On the contrary, it is entangled with the lunar parallax, the constants of precession and nutation, the parallactic inequality of the moon, the lunar inequality of the earth, the masses of the earth and moon, the ratio of the solar and lunar tides, the constant of aberration, the velocity of light, and the light equation." It should therefore be determined simultaneously with all these quantities by means of a least-square adjustment, and Prof. Harkness develops such a method. The equations connecting the constants are given, whilst the numerical values which are discussed are based upon an enormous mass of astronomical, geodetic, gravitational, and tidal observations which have required more than two hundred years for their accumulation. The sources of probable error are also examined, and it is suggested how some of the constants may be improved in the future. The completeness of the lists of constants, and the careful manner in which they are discussed and corrected by the comprehensive least-square adjustment which is developed, justifies our giving *seriatim* the results obtained:—

Equatorial semi-diameter of the earth—

3963·124 ± 0·078 miles.

Polar semi-diameter of the earth—

3949·922 ± 0·062 miles.

One earth quadrant—

10001816 ± 125·1 metres.

Oblateness or flattening of the earth—

1/300·205 ± 2·964.

Eccentricity of the earth—

0·006651018.

Mean density of the earth—

$$5{\cdot}576 \pm 0016.$$

Surface density of the earth—

$$2{\cdot}56 \pm 0{\cdot}16.$$

Length of the seconds pendulum (ϕ = latitude)—

$$39{\cdot}012540 + 0{\cdot}208268 \sin^2\phi \text{ inches.}$$

Acceleration due to gravity—

$$32{\cdot}086528 + 0{\cdot}171293 \sin^2\phi \text{ feet.}$$

Length of the sidereal year—

$$365\text{d. } 6\text{h. } 9\text{m. } 9{\cdot}314\text{s.}$$

Length of the tropical year at time t—

$$365\text{d. } 5\text{h. } 48\text{m. } 46{\cdot}069\text{s.} - 0{\cdot}53675\text{s.} \left(\frac{t - 1850}{100}\right).$$

Length of the sidereal month—

$$27\text{d. } 7\text{h. } 43\text{m. } 11{\cdot}524\text{s.} - 0{\cdot}022671\text{s.} \left(\frac{t - 1800}{100}\right).$$

Length of the synodical month—

$$29\text{d. } 12\text{h. } 44\text{m. } 2{\cdot}841\text{s.} - 0{\cdot}026522\text{s.} \left(\frac{t - 1800}{100}\right).$$

Length of the sidereal day—

$$86164{\cdot}09965 \text{ mean solar seconds.}$$

Ratio of the mean motions of the sun and moon—

$$0{\cdot}074801329112.$$

Mass of Mercury (Sun = 1), $\frac{1}{8374672 \pm 1765762}$

" Venus " $\frac{1}{408968 \pm 1874}$

" Earth " $\frac{1}{327214 \pm 624}$

" Mars " $\frac{1}{3093500 \pm 3295}$

" Jupiter " $\frac{1}{1047{\cdot}55 \pm 0{\cdot}20}$

" Saturn " $\frac{1}{3501{\cdot}6 \pm 0{\cdot}78}$

" Uranus " $\frac{1}{22600 \pm 36}$

" Neptune " $\frac{1}{18780 \pm 300}$

" Moon (Earth = 1) $\frac{1}{81{\cdot}068 \pm 0{\cdot}238}$

Constant of solar parallax—

$$8''{\cdot}80905 \pm 0''{\cdot}00567.$$

Mean distance of earth from sun—

$$92796950 \pm 59715 \text{ miles.}$$

Eccentricity of the earth's orbit—

$$0{\cdot}016771049.$$

Lunar inequality of the earth—

$$6''{\cdot}52294 \pm 0''{\cdot}01854.$$

Lunar parallax—

$$3422''{\cdot}54216 \pm 0''{\cdot}12533.$$

Mean distance from earth to moon—

$$238854{\cdot}75 \pm 9{\cdot}916 \text{ miles.}$$

Eccentricity of moon's orbit—

$$0{\cdot}054899720.$$

Inclination of moon's orbit—

$$5^\circ\ 8'\ 43''{\cdot}3546.$$

Mean motion of the moon's node in 365¼ days—

$$-19^\circ\ 21'\ 19''{\cdot}6191 + 0''{\cdot}14136 \left(\frac{t - 1800}{100}\right).$$

Parallactic inequality of the moon—

$$124''{\cdot}95126 \pm 0''{\cdot}08197.$$

Constant of luni-solar precession—

$$50''{\cdot}35710 \pm 0''{\cdot}00349.$$

Constant of nutation—

$$9''{\cdot}22054 \pm 0''{\cdot}00859.$$

Constant of aberration—

$$20''{\cdot}45451 \pm 0''{\cdot}01258.$$

The time taken by light to traverse the mean radius of the earth's orbit (the light equation)—

$$498{\cdot}00595\text{s.} \pm 0{\cdot}30834\text{s.}$$

The velocity of light *in vacuo* per second of mean solar time—

$$186337{\cdot}00 \pm 49{\cdot}722 \text{ miles.}$$

In order to improve the system of constants discussed, Prof. Harkness thinks that the parallax of the moon should be determined by the diurnal method at one or more stations as near as possible to the equator, and that the Observatories in the northern and southern hemispheres should co-operate with each other for two or three years in systematically making meridian observations of the moon to improve our knowledge of its parallax. Numerous pendulum observations are required, and new determinations of the constants of aberration and nutation by as many different methods as possible. The most probable coefficient of the lunar inequality of the earth's motion should be obtained from Greenwich and Washington meridian observations of the sun, whilst the opposition of Mars in 1892, and favourably situated asteroids, should be utilized for new determinations of the solar parallax.

The laborious character of an investigation which leads to the results here given is patent to all. To say, therefore, that all the computations involved were made and checked by Prof. Harkness himself is to testify to industry very rarely excelled.

TECHNICAL EDUCATION IN RUSSIA.

An interesting report on technical education in Russia has been laid before Parliament by the Foreign Office. It is a digest by Mr. Harford of a very voluminous Report, compiled by Mr. Anopoff, Director of the Nicholas Industrial School at St. Petersburg, on technical education in Russia, and is described by Sir R. Morier as giving an exhaustive review of all that has been done during the last 20 years in Russia in this important branch of national education, and is of special interest as furnishing information on the most recent legislation respecting schools about to be founded.

M. Anopoff confines himself to giving full details of intermediate and elementary technical and industrial teaching institutions, without attempting a description of the higher schools. The establishment of these former classes of schools dates, he says, from only some 25 years back, but in that short space of time they have spread to the confines of the Russian Empire. In 1883, a special section for technical and professional education was created in the Ministry of Education. According to the new regulations of the *Realschulen*, intermediate and elementary technical and industrial schools are to be opened at the public expense. M. Anopoff remarks, however, that these new schools cannot be expected to be at first as successful as the existing schools with their long practical experience. He adds, too, that the greater number of the technical schools in Russia were founded at the initiative, and often even at the expense, of local societies and private persons. The various technical and industrial institutions in Russia are divided into five groups:—(1) Technical schools with the course of intermediate schools resembling the *Realschulen*, but differing from them by their professional character being more strongly marked. The task of these schools, which, as regards the knowledge required, is about equivalent to the standard of the *Realschulen*, with a course of from six to eight years, consists in imparting a general acquaintance with the technical and partly commercial subjects which are indispensable for the assistants of engineers, and for independent managers of small technical undertakings. (2) To the second group may be referred institutions in which subjects of general education are taught within the scope of the courses of municipal schools and district and village schools with two classes. From those who enter them a knowledge is required approximate to the scope of primary schools, the full course of study lasting from four to six years. In these schools, besides the subjects taught in the municipal schools under the regulations of 1872, the following additional subjects are taken up: physics, mechanics, technology of metals and woods, bookkeeping, &c., while to drawing, both freehand and geometrical, much attention is given. The object of these institutions is the preparation of skilled artisans for factories, of lesser mechanical specialists, machinists, and draughtsmen. In this category should be included the railway schools, but as they are under the control of the Ministry of Communications, and serve certain special objects exclusively connected with railways, no account of them is given. (3) Industrial schools with a course of general education not exceeding the scope of the course of primary schools, or sometimes reaching the standard of the second class in village schools with two classes. In most of them pupils are received who have completed the course in the public school, and who repeat what they have gone through in it. These schools are founded with the object of preparing skilled artisans for village and domestic industries, and also factory hands. They contain workshops for joiners, blacksmiths, carpenters, fitters, tailors, shoemakers, saddlers, bookbinders, &c.; but few of these institutions can boast of a systematic course of instruction in trades. (4) To this group belong various special and general educational schools for adults, as the school for foremen builders, the school for printers, the evening and Sunday special classes of the Imperial Technical Society at St. Petersburg, the Riga Industrial School, &c. The teaching in these institutions takes place in the evenings of week-days, and on Sundays, *i.e.* when the adult workmen for whom they are intended are free from their work. (5) This group consists of elementary schools of general education, *i.e.* primary, district, or municipal schools with supplementary industrial sections. It is worthy of notice that persons who have gone through the whole course, or at least reached a certain standard, at any of the schools of these five groups, enjoy certain privileges with regard to exemption from military service.

The report then goes on to describe in detail the courses of some of the leading industrial schools as types of the different groups, as well as of the industrial classes attached to the elementary schools. In conclusion, the report summarizes the more important provisions of the ukase of March 7/19, 1888, respecting the conditions under which technical and industrial schools may be opened in Russia, either wholly or in part, at the expense of the State (given in Appendices I., II., III.). The cost of maintenance of these schools is respectively estimated in the ukase as follows: the intermediate mechanical technical schools at 27,311r. (£2730) per annum; the elementary mechanical technical schools at 19,436r. (£1945) per annum; and the trade schools at 11,960r. (£1200) per annum. The Ministry of Education has assigned for this year the sum of £50,000 for the creation of these technical schools, and it is reported that the Ministry has been urged to devote a considerable portion of this sum to founding schools in the districts where village industries prevail, the richer manufacturing districts being better able to dispense with State aid. The provisions of the ukase are:—(1) The industrial schools for the male inhabitants of the Empire exist for the purpose of diffusing among the population technical education of the intermediate and elementary standards, as well as instruction in handicrafts. (2) The intermediate technical schools impart the instruction and skill indispensable to artificers who are destined in time to act as the trusted assistants of engineers and of other managers of industrial enterprises. (3) The elementary technical schools, besides initiation into the mysteries and methods of some one definite handicraft, likewise impart the knowledge and skill indispensable to men whose duty it will in time become to act as master-workers and immediate overseers of the operations of artisans in industrial establishments. (4) The trade schools exist for the purpose of giving practical tuition in the methods of any one trade, and at the same time of communicating such knowledge and skill as are absolutely necessary to the intelligent execution of the work of such trade. (5) Industrial schools of each of the above-mentioned categories can exist either apart or in conjunction with other similar schools of various degrees and specialities. (7) The industrial schools are supported at the expense of the Crown, or of the *zemstvos*, societies, guilds, or private individuals, or by funds contributed simultaneously from all these sources. (8) The course in the intermediate technical schools is not to exceed four years; that of the elementary and trade schools three years. (9) Those who enter trade schools are required to produce a certificate of their having gone through the course of an elementary school; those who enter the elementary technical schools, a certificate of having gone through the course in a municipal school, or village school, with two classes; while those who enter intermediate technical schools must have gone through five classes of a *Realschule*. (10) Those who are unable to satisfy the conditions mentioned in the preceding paragraph, but who have worked not less than two years in industrial institutions, and have proved that they can successfully follow the course at the school they wish to enter, may be also admitted. (11) Industrial schools must have: (*a*) a library, (*b*) a room with appliances for geometrical and freehand drawing, (*c*) where possible a room with appliances for modelling, (*d*) the necessary school books for the special object for which the school is intended, and in addition the requisite appliances for the practical work of the apprentices. (14) Pupils who have successfully completed their education in an intermediate technical school, after a four years' course, receive the appellation of artificer in their specific calling. Those who have only gone through a two or three years' course, only receive this appellation after three or two years respectively, spent uninterruptedly in industrial work. Those who are so styled obtain certain privileges as regards their civil status and in respect to military service, and they enjoy in addition the right of entering the higher technical schools. Those who have completed the course at the other two categories of schools enjoy the privileges as regards civil status and military service which correspond to the general education they have received.

FOSSIL FISH OF THE SCANDINAVIAN CHALK.

MR. DAVIS has availed himself of the opportunities presented to him by the chief officers of the Museums of Lund, Stockholm, and Copenhagen, and has published a monographic account of the fish remains from the Cretaceous formations of Scandinavia.

Over seventy years ago Sven Nillson first discovered fish remains in the Swedish chalk. Since then numerous large collections have been made by the officers of the Geological Survey of Sweden and others, and the greater number of these specimens were unreservedly placed at the disposal of Mr. Davis for description in his memoir; he has also had the opportunity of consulting some smaller collections in Sweden, and most of the forms have been figured from the original specimens by Mr. Crowther.

These fish remains show a closer relationship to the Cretaceous fish remains of the north of Europe, as represented by the English and French chalk fish, than to the more highly specialized chalk fauna of Asia Minor, but they do not afford representatives of several of the Physostomous Teleosteans, such as Ichthyodectes, Protosphyræna, and Pachyrhizodus, which have been found in the English chalk, and have also occurred in the Upper Cretaceous rocks of North America.

The great majority of the fish remains are Selachian, and comprise twenty-four species. Of these, *Carcharodon rondeletii*, *Otodus obliquus*, and *Odontaspis acutissimus* are regarded as indicating a Tertiary fauna, but in the Scandinavian chalk they have been found asoociated with many undoubted Cretaceous forms in the Faxe limestone or chalk. The character and extent of this fauna indicates conditions very similar to those accompanying the deposition of the English and French chalk and of that of Central Europe generally, whilst it affords comparatively few data for comparison with that of Lebanon. The occurrence of numerous teeth of several species of Scapanorhynchus in the Swedish area is worthy of note, but the fish are not found preserved bodily as they are in the chalk of Lebanon.

This memoir is published as Part vi. of vol. iv. of the Transactions of the Royal Dublin Society, and is illustrated with an atlas of nine plates.

SOCIETIES AND ACADEMIES.

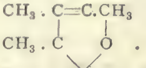
LONDON.

Royal Society, May 28.—"On the Bases (Organic) in the Juice of Flesh. Part I." By George Stillingfleet Johnson, M.R.C.S., F.C.S., F.I.C. Communicated by Prof. G. Johnson, F.R.S.

The author has endeavoured to ascertain by careful experiments how far the substances hitherto prepared from flesh are true "*educts*," and really present in the flesh itself, or merely products, due to (1) the action of chemical or physical agencies applied in the course of extraction, or (2) to bacterial action modifying the composition of the flesh before it comes into the hands of the operator.

The final conclusion drawn is that sarcous kreatine is not present in fresh muscle, but results from bacterial action whereas sarcous kreatinin is probably a true "educt."

Chemical Society, May 7.—Dr. J. H. Gladstone, F.R.S., Vice-President, in the chair.—The following papers were read:—The action of alkalis on the nitro-compounds of the paraffin series, by W. R. Dunstan and T. S. Dymond. The paper contains the results of further investigation of the interaction of alkalis and nitroethane, of which a preliminary account has already been given (Chem. Soc. Proc., 1888, p. 117). Nitroethane and alkali carbonates in the cold interact to yield carbon dioxide, and the alkali derivative of nitroethane, which is obtained when alkali hydroxide is employed. Ammonia combines with nitroethane in the cold to form a crystalline compound, analogous to the potassium and sodium derivatives. The action of alkalis proceeds further on warming, and there are formed alkali nitrite, acetonitrile, and a compound, boiling at 171°, and solidifying to a crystalline mass when cooled to 3°·5. The authors find that this compound is trimethylisoxazole



It is very stable, and is almost unaffected by heating in closed tubes with strong acids and alkalis. Permanganate oxidizes it to acetic acid, and nitric acid to acetic and oxalic acids. By reducing-agents it is slowly decomposed with formation of ammonia, acetic acid, and secondary butyl alcohol. By the action of sodium on a well-cooled moist ethereal solution, a *dihydride* $C_6H_{11}NO$ (m.p. 110°) is formed, which, when heated with water, is decomposed into ammonium acetate and ethyl methyl ketone. The *mercurichloride* has the formula C_6H_9NO, Hg_2Cl_2, and the *aurichloride* the formula $C_6H_9NO, AuCl_3$. Nitropropane, when acted on by alkalis, yields triethylisoxazole, propionitrile, and alkali nitrite, but the reaction occurs with greater difficulty than in the case of nitroethane. Nitromethane is readily acted on by alkalis, and hydrogen cyanide, alkali nitrite, and much resin are formed. The parent isoxazole could not be isolated. Secondary nitropropane is attacked with difficulty by alkalis, and no isoxazole is formed.—Some new addition compounds of thiocarbamide which afford evidence of its constitution, by J. E. Reynolds, F.R.S. Thiocarbamide combines with ammonium bromide, iodide, and chloride at the temperature of boiling alcohol, and forms compounds of the type $(H_4N_2CS)_4H_4NR'$. Under the conditions specified no compounds were obtained containing less than four molecular proportions of the amide to one of the ammonium haloid salt. Methyl-, ethyl-, allyl-, phenyl-, diphenyl-, and acetylphenyl-thiocarbamides do not yield compounds with ammonium bromide at the temperature of boiling alcohol. Thiocarbamide and tetrethylammonium bromide and iodide yield compounds of the type $(H_4N_2CS)_2Et_4NR'$. Under the experimental conditions, no well-defined substance was obtained containing more than two molecular proportions of the amide to one of the tetrethylammonium salt. Thiocarbamide and diethylammonium bromide form the compound $(H_4N_2CS)_3Et_2H_2NBr$. Thiocarbamide, when treated with triethylammonium bromide yields a mixture of the two compounds $(H_4N_2CS)_3Et_3HNBr$ and $(H_4N_2CS)_2Et_3HNBr$. With methylammonium bromide the amide forms the compound $(H_4N_2CS)_4MeH_3NBr$. It does not, however, combine with ethylammonium bromide, and when heated with the salt in the molecular proportions 4 : 1 at 135° in a sealed tube, together with alcohol, it yielded ethyl oxide and tetrathiocarbamidammonium bromide. The author points out that these facts supply evidence against the symmetrical constitution of thiocarbamide $CS(NH_2)_2$, and altogether in favour of the unsymmetrical constitution $HN : C(SH)NH_2$.—The action of acetic anhydride on substituted thiocarbamides; and an improved method for preparing aromatic mustard oils, by E. A. Werner, Trinity College, Dublin. The action of acetic anhydride on diphenyl-, ortho-, meta- and para-ditolyl-, meta-dixylyl-, dibenzyl- and diethyl-thiocarbamides has been studied. In the case of the aromatic derivatives, no acetylated derivatives of the thiocarbamides were produced. The solution of the thiocarbamide in acetic anhydride is accompanied by simultaneous decomposition into "anilid" and mustard oil in accordance with the equation $CS(NHR)_2 + (CH_3CO)_2O = CH_3CONHR + R.NCS + CH_3COOH$. When the solution is heated for five minutes at the boiling-point of acetic anhydride, an almost theoretical yield of mustard oil is obtained. Prolonged heating produces a secondary reaction expressed by the equation $R . NCS + CH_3COOH = CH_3CONHR + COS$. In the case of fatty thiocarbamides a well-defined acetylated thiocarbamide is first produced, and prolonged heating gives rise to the formation of mustard oil, but the yield of the latter is never high, and as final product a substituted amide is produced.—The decomposition of silver chloride by light, by A. Richardson. When pure silver chloride is exposed to light under water oxygen is evolved, part of which is present as ozone; when small quantities of water are present, chlorine and hydrogen chloride are found in solution; with large quantities of water, hydrogen chloride, but no chlorine, is found. The influence of hydrogen chloride in retarding the decomposition of silver chloride is considered, and is explained from experimental results given, which show that even minute quantities of hydrogen chloride exercise a marked influence on the stability of chlorine water when exposed to light, the rate of decomposition of the silver chloride being dependent on the readiness with which the chlorine in solution and water interact to form hydrogen chloride. The author describes experiments which show that the darkened product obtained by exposure of silver chloride to light contains no oxygen, and he concludes that it is of the nature of a sub-chloride rather than an oxychloride.—The addition of the elements of alcohol to the ethereal salts of unsaturated acids, by T. Purdie and W. Marshall. The authors record the results of experiments on the addition of the elements of alcohol to ethereal salts of fumaric and maleic acids by the agency of small quantities of sodium alkylate; they also describe a series of experiments with other ethereal salts, the object of which was to ascertain if the ethereal salts of unsaturated acids in general are capable of undergoing the same additive change. By the action of a small quantity of sodium methylate in the cold, on a mixture of methylic alcohol and methylic fumarate, an almost theoretical yield of methylic methoxysuccinate is obtained. Methyl fumarate, on heating with alcoholic sodium methylate, yielded a compound of the formula $C_{11}H_{12}O_7$, formed by the abstraction of 3 mols. of methyl alcohol from 2 mols. of methylic methoxysuccinate. Under similar conditions methylic amylate gave methylic methylpropionate. Methylic and ethylic crotonate gave methylic methoxybutyrate and ethylic ethoxybutyrate. The authors think that the alkyloxy-group attaches itself to the β-carbon atom. Ethylic methacrylate also formed additive compound; but pure products were not obtained from the reaction. Ethylic angelate, ethylic allylacetate, methylic and ethylic cinnamate and ethylic *o*-(β) ethylcumarate do not undergo additive change.—Notes on the azo-derivatives of β-naphthylamine, by R. Meldola, F.R.S., and F. Hughes. The authors have completed the series of azo-derivatives obtainable from the nitranilines and β-naphthylamine by preparing orthonitrobenzene azo-β-naphthylamine. The latter by the action of nitrite in a warm acetic acid solution gives orthonitrobenzeneazo-β-naphthol. In cold acetic acid solution the naphthyl acetate is formed. Acetyl derivatives of the ortho-, meta-, and para-nitroazo-derivatives of β-naphthylamine have also been prepared. The pseudazimides from the para- and metanitro-compounds have been prepared. These compounds have the formula  $C_{10}H_6\left\langle\begin{matrix}N\\ \vdots\\ N\end{matrix}\right\rangle N . C_6H_4 . NO_2$ (*p* or *m*). The action of aldehydes on these β-naphthylamine azo-derivatives gives rise to the formation of triazines, which are being investigated.—A method for the estimation of nitrates, by G. McGowan, Ph.D. This estimation is based on the interaction $HNO_3 + 3HCl = NOCl + Cl_2 + 2H_2O$. The gaseous products are led into a solution of potassium iodide.—New benzylic derivatives of thiocarbamide, by A. E. Dixon, M.D. A re-examination of "monobenzyl-thiocarbamide" has shown that the substance hitherto bearing this name is benzylamine thiocyanate; the latter can be converted into the isomeric thiocarbamide by heating for a short time at 150°–160°. The author describes a great number of benzylic derivatives of thiocarbamide.

Linnean Society, May 24.—Anniversary Meeting.—Prof. Stewart, President, in the chair.—The Treasurer presented his Annual Report duly audited, and the Secretary having announced the elections and deaths during the past twelve months, the usual ballot took place for new members of Council, when the following were elected: Messrs. C. B. Clarke, G. B. Howes, Arthur Lister, St. G. Mivart, and F. W. Oliver. The President and officers were re-elected. The usual formal business having been transacted, the President proceeded to deliver his annual address, taking for his subject "The Secondary Sexual Characters of Animals and Plants," of which he gave several interesting examples, illustrating his remarks with graphic sketches in coloured chalks. On the motion of Mr. H. Druce, seconded by Mr. C. Tyler, a vote of thanks was accorded to the President for his able address, with a request that he would allow it to be printed.—The Linnean Society's Gold Medal for the year 1891 was then formally awarded to Dr. Edouard Bornet, of Paris, for his researches in botany, and on his behalf was presented to M. Raymond Lecomte, Secretary to the French Embassy. The proceedings then terminated.

Institution of Civil Engineers, May 26.—Annual General Meeting.—Sir John Coode, K.C.M.G., President, in the chair.—In the Report of the Council for the session 1890–91, it was remarked that the salient feature of the session, now terminated, had been the realization of a proposal made more than forty years ago—namely, the formal reception by the President and Council on stated evenings after the ordinary meetings of the members and visitors then present. A series of receptions was held after the ordinary meetings in the months of January, February, March, April, and May, of this year. An endeavour has also been made to identify, in some degree, each gathering with a particular branch of engineering, both in respect to those invited to be present and to the models and other objects of interest exhibited. These receptions were believed to have been most successful, and experience would doubtless suggest directions in which they might be rendered still more useful and attractive in the future. The effective increase in the roll of the Institution during the past year was 247. The number of members of all classes, students excepted, on March 31 last, was 5150, as against 4903 on the same day last year, representing an increase at the rate of 5 per cent.—The adoption of the Report was moved, seconded, and carried, and it was ordered to be printed in the Minutes of Proceedings. Cordial votes of thanks were then passed to the President, to the Vice-Presidents and other Members of the Council, to the Auditors, to the Secretaries and Staff, and to the Scrutineers.—The ballot for Council resulted in the election of Mr. George Berkley as President; of Mr. H. Hayter, Mr. A. Giles, M.P., Sir Robert Rawlinson, K.C.B., and Sir Benjamin Baker, K.C.M.G., as Vice-Presidents; and of Mr. W. Anderson, D.C.L., Mr. J. Wolfe Barry, Mr. E. A. Cowper, Sir Jas. N. Douglass, F.R.S., Sir Douglas Fox, Mr. J. Clarke Hawkshaw, M.A., Mr. Charles Hawksley, Sir Bradford Leslie, K.C.I.E., Mr. George Fosbery Lyster, Mr. J. Mansergh, Sir Guilford Molesworth, K.C.I.E., Mr. W. H. Preece, F.R.S., Sir E. J. Reed, K.C.B., F.R.S., M.P., Mr. W. Shelford, and Mr. F. W. Webb as other Members of the Council.—The session was adjourned until the second Tuesday in November, at 8 p.m. [At the first meeting of the newly-elected Council, the following officers were re-appointed: Mr. H. L. Antrobus, as Treasurer; Dr. Wm. Pole, F.R.S., Honorary Secretary; and Mr. James Forrest, the Secretary.]

EDINBURGH.

Royal Society, May 4.—Sir Douglas Maclagan, President, in the chair.—A preliminary note by Mr. John Aitken, on a method of observing and counting the number of water particles in a fog, was communicated. The phenomena which are denoted by the names fog, mist, and rain, differ merely in degree, and not in kind. In a haze dry dust particles are present in the air to a greater or less extent. The haze turns into a fog when water vapour is condensed upon the particles, and the fog will develop into mist upon the condensation of a sufficient amount of moisture. So that we may regard an ordinary fog and a mist as a dry fog and a wet fog respectively. The water drops in a fog will gradually settle upon the exposed surfaces of bodies. Hence it might seem that, in order to determine the extent to which moisture is present in a fog, it would be sufficient to allow the drops to fall upon a piece of mirror, which they would soon wet. But Mr. Aitken has found that when exposed surfaces are quite dry, a great quantity of water drops are often present in the air. The drops are exceedingly small and evaporate with great rapidity from the surfaces (heated by radiation) upon which they fall. The instrument which Mr. Aitken has adopted for the purpose of determining whether or not water drops are present is essentially identical with his pocket-dust counter. It consists of a glass micrometer divided into squares of a known size, a spot mirror for illuminating the stage, and a strong lens or a microscope for observing the drops on the stage. It is found convenient to observe an area of the stage equal to about 1/16th or 1/20th square centimetre when working with a magnifying lens. In one fog which was observed, objects at a greater distance than 100 yards were quite invisible, and the surfaces of exposed objects were quite dry. The number of drops which fell per minute varied greatly, sometimes reaching 3000 per square centimetre, sometimes only 300 per square centimetre. Two days later the same apparent external conditions regarding fog again obtained, and the number was found to be 1300 per square centimetre per minute—which remained fairly constant until the fog began to clear off when it slowly diminished. In both cases the observation was made at 10 a.m. If the stage be slightly heated, the drops never reach the surface but evaporate in the layer of heated air over it. Mr. Aitken has also modified this apparatus in order to admit of the counting of the number of drops which fall from a column of air of known height. A low power microscope is used, and so a column of air 5 centimetres long can be obtained over the stage. Underneath, and concentric with the microscope, a tube 5 centimetres long and 4 centimetres in diameter is mounted. The top and bottom of this tube can be simultaneously closed by covers which turn on an axis parallel to the axis of the tube. A micrometer, illuminated by a spot mirror, is fixed in the centre of the bottom, and, in the centre of the upper cover, a small opening which corresponds to the lens of the microscope is made. The former instrument may be used to observe the larger particles of dust in the atmosphere.—Dr. J. M. Macfarlane read a paper, illustrated by lantern demonstrations, on a comparison of the minute structure of plant hybrids with that of their parents. He finds that the minute structure of the hybrid, like the larger features, is always intermediate in character between the corresponding structures of the parents.

PARIS.

Academy of Sciences, May 25.—M. Duchartre in the chair.—Researches on the camphene series, by MM. Berthelot and Matignon.—Researches on the vapour-tension of saturated water-vapour at the critical point, and on the determination of this critical point, by MM. Cailletet and Colardeau. In a recent note (*Comptes rendus*, vol. cxii. p. 563, 1891) the authors communicated to the Academy a new method for determining critical temperatures and pressures. They now give the results obtained in the case of water. Six series of experiments with different weights of water indicate that the critical temperature is 365° C., the critical pressure which corresponds to this being 200·5 atmospheres.—On the analysis of the sunlight diffused by the sky, by M. A. Crova. If B be the intensity of the blue light diffused by the sky, and S the intensity of incident sunlight, it may be shown that $\frac{B}{S} = 100\left(\frac{565}{\lambda}\right)^n$, where 565 represents the wave-length of the maximum light intensity of the spectrum, and n is an empirical coefficient. M. Crova calculates values with $n = 4$ and $n = 4·5$, and finds that, although Lord Rayleigh's observations (*Phil. Mag.*, 1871, p. 107) are best in accord in the former case, his own observations at Montpellier give results which are better represented when the latter value of n is used.—On the relative age of the Quaternary stratum of Mont Dol (Ille-et-Vilaine), by M. Sirodot. The author's observations lead him to believe that the *débris* on Mont Dol belongs to an epoch anterior to the movement which in Quaternary times elevated the coasts of certain regions of the Baltic Sea.—On the exact determination of the glycolitic power of the blood, by M. R. Lépine and Barral.—Observation of the passage of Mercury across the sun's disk on May 9, 1891, made with the Plœssl equatorial at the National Observatory of Athens, by M. D. Eginitis. The internal contact of egress occurred at 18h. 17m. 20s., and external contact at 18h. 22m. 0s. (Athens mean time). The irradiation phenomenon known as the "black drop" was not observed.—The atmospheric conditions of Greenwich with regard to the universal hour question, by M. Tondini. The cloudy state of the Greenwich sky, and the many rainy days recorded at the Observatory, are adduced as arguments against the adoption of Greenwich as the prime meridian. The meridian of Jerusalem-Nyanza is said to possess numerous atmospheric and other advantages.—On the algebraic integration of differential equations of the first order, by M. Painlevé.—On the determination of the integrals of equations from derived partials of the first order, by M. J. Collet.—On Abelian equations, by M. A. Pellet.—Researches in thermo-electricity, by MM. Chassagny and Abraham.—Determination of the solar constant, by M. R. Savélief. From an actinometric curve obtained on December 26, 1890, the author obtains for the solar constant, reduced to the mean distance of the sun from the earth, the value 3·47 calories. Langley's value, from his Mount Witney observations, was 3·0 calories.—On the fluctuations in the heights of lake waters, by M. P. du Boys. In lakes, and particularly in the Lake of Geneva, the surface of water regularly rises in one part and lowers in another, performing an oscillatory movement. The region where the level is practically constant is called the node, and the movements referred to go by the name of *seiches*. The author investigates this wave-motion mathematically.—On a new portable sounding-apparatus of steel wire, by M. Émile Belloc.—Study of the barometric gradient, by M. G. Guilbert. Some remarkable relations between the force of the wind and the barometric gradient are given.—Relation between atomic weight and the density of liquids, by M. Al. Moulin.—On the sub-chloride of silver, by M. Guntz. Under the action of heat, the sub-chloride decomposes into silver and silver chloride. This decomposition is easily seen by the change of colours of the sub-chloride. Dilute nitric acid has absolutely no action upon the compound. With hot concentrated nitric acid, chloride of silver mixed with the sub-chloride is obtained. Potassium cyanide rapidly dissolves the compound, and decomposes it. Utilizing this reaction, the author has found that a given weight of chlorine disengages practically the same amount of heat (29 calories), when combining with Ag as when combining with Ag_2.—Action of potassium salts upon the solubility of potassium chlorate, by M. Ch. Blarez.—Electrolysis of the fused salts of boron and silicon, by M. Adolphe Minet. Some interesting experiments indicate that, by the electrolysis of white and red bauxites, it is possible to produce a series of alloys of iron, silicon, and aluminium, and, at the end of the operation, to obtain aluminium chemically pure.—On two new crystalline compounds of platinic chloride with hydrochloric acid, by M. Léon Pigeon. The compounds described have the composition $PtCl_4 . 2HCl . 4H_2O$ and $PtCl_4 . HCl . 2H_2O$.—On salicylate of bismuth, by M. H. Causse.—On the heat of solution and the solubility of some bodies in methyl-, ethyl-, and propyl-alcohols, by M. Timofeiew.—On the Stelleridæ found in the Bay of Biscay, at the Azores, and Newfoundland during the scientific expeditions of the yacht *Hirondelle*, by M. Edmond Perrier.—On the equivalence of the bundles in vascular plants, by M. P. A. Dangeard.—On the trappean formation of Toungouska Pierreuse, Siberia, by M. K. de Kroustchoff.—Researches on the elimination of oxide of carbon from the system, by M. L. de Saint-Martin.

Melbourne.

Royal Society of Victoria, March 12.—The following officers were elected for the year 1891:—President: Prof. Kernot. Treasurer: C. R. Blackett. Secretaries: H. K. Rusden and Prof. W. Baldwin Spencer.—The following papers were read:—A new species of Dictyonema, by T. S. Hall.—A preliminary account of *Synute pulchella*, by Arthur Dendy. This is a new genus and species of calcareous sponge, which is allied to Ute, but in which the individuals are fused together into a common mass.—The geology of the southern portion of the Moorabool valley, by T. S. Hall and G. B. Pritchard.

April 9.—On the occurrence of the genus Belonostomus in the Rolling Downs formation (Cretaceous) of Central Queensland, by R. Etheridge, Jun., and Arthur Smith Woodward, of the British Museum. This is described as a new species, under the name of *Belonostomus sweeti*.—Note on a new genus of Chætopod worm parasitic on a sponge of the genus Rhaphidophlus from Port Phillip, by Prof. W. Baldwin Spencer. The worm is remarkable in having the dorsal surface covered with a series of rows of setæ, each row enclosed in a membranous web, the bunches of setæ on the feet are also enclosed in webs.

Göttingen.

Royal Academy of Science.—In the Journal of the Scientific Academy of Göttingen, the following papers of scientific interest appear (July to December, 1890):—

July.—Fr. Pockels: On the interference phenomena of convergent homogeneous polarized light through twin-plate uniaxal crystals.—Voigt: Determination of the elastic constants of Brazilian tourmaline.

August.—Julius Weingarten: On particular integrals of Laplace's equation, and a class of fluid motions connected with the theory of minimum surfaces.—Venske: A modification of Hermite's first proof that *e* is transcendental.—Riecke: Special cases of equilibrium of a system having several phases.—Meyer: Discriminants and resultants of singularity equations (second notice).—Burkhardt: An equation in the theory of the theta-functions.—Klein: On the zero-points of the hypergeometric series.

October.—Nernst: On the distribution of a substance between two solvents.

December.—Riecke: The thermal potential of weak solutions. On electricification by friction.—Meyer: On discriminants and resultants of singularity equations (third notice).—Voigt: On the vibrations of strings.—Riecke: Molecular theory of diffusion and electrolytic conduction.—Hurwitz: On the zero points of the hypergeometric series.—Voigt: Determination of the constants of elasticity of several non-crystalline minerals.—Auerbach: On hardness and its absolute measurement.

Stockholm.

Royal Academy of Sciences, May 13.—The elements of the hydrography of the Kattegatt and Skagerack, by Prof. O. Pettersson.—Studies on the Solenogastres; i. monograph of *Chætoderma nitidulum*, by Dr. A. Wirén.—Researches on the fossil wood of Sweden, by Dr. Conwentz, in Danzig.—Prof. S. Lovén gave a report on the work executed during the last summer at the zoological station of Kristineberg in Bohuslän, Sweden, and reviewed a paper by Dr. C. Aurivillius on the symbiosis between Pagurus and Hydractinia as well as another by Dr. Wirén on *Chætoderma nitidulum*.—Researches and observations on the method of Koch in treating tubercular diseases by Prof. Bruzelins.—A copper-plate engraving of a map of the world made in the beginning of the fifteenth century, formerly belonging to the museum of Cardinal Borgia in Velletri, described by Baron A. E. Nordenskiöld.—Studies on the brain of teleosteous fishes, by Herr G. Andersson Malme.—A final contribution to the flora of the Chlorophyllophysæ of Siberia, by Herr O. F. Borge.—On phen-ethyl-propyl and phenyliso-propyl-triazol combinations by Dr. T. A. Bladin.—On the specific heat of water between 0° and + 40°, by Herr A. M. Johansson.—A few formulæ to calculate the mortality among annuitants of public offices and private societies by Dr. G. Enström.—A comparison between the methods of Ångström and Neuman for determining the conductibility of heat in bodies; ii. experimental researches, by Dr. Hagström.—Hydrographical researches in the Gullman fiord during the summer of 1890, by Miss A. Palmqvist.

MAMMALS LIVING AND EXTINCT.

An Introduction to the Study of Mammals Living and Extinct. By W. H. Flower and Richard Lydekker. (London: Adam and Charles Black, 1891.)

THIS work is, as the authors inform us in the preface, based largely upon the article Mammalia, together with forty shorter articles, written by Prof. Flower for the ninth edition of the "Encyclopædia Britannica." Certain other articles by Dr. Dobson and Dr. St. George Mivart have also been made use of. The illustrations, most of which are admirable, are chiefly those prepared for the "Encyclopædia," but many have been added. Mr. Oldfield Thomas, of the British Museum, has assisted the authors in special matters. To Mr. Lydekker fell the task of arranging the various articles made use of in proper sequence, filling up gaps and adding new matter, a large amount of which treats of the extinct forms.

The book resulting from this process is undoubtedly one which will be found interesting and useful by all students of zoology. There is a great deal in it which is worth reading; especially so are the four introductory chapters on general anatomical characters, origin and classification of the Mammalia, and on geographical and geological distribution. Moreover, with regard to important animals such as the horse, sheep, goat, pig, a great deal of accurate information of varied character is given. The whales are, as we should expect, treated with special mastery, and throughout the book we come upon pages which are models of lucid statement and judicious selection of matter.

It should, however, be clearly understood that the book is not and does not profess to be a complete work of reference on the Mammalia. The references to extinct groups are exceedingly scanty, and whilst they serve to stimulate the reader's desire for further information, do not, as a rule, furnish him with the titles of original works in which such information is to be found. The bulk of the work consists of chapters treating of the orders of Mammalia in systematic sequence, and there is no doubt that, both for the general reader and for the more technical zoologist, they form a mine of valuable information well up to date, and as a rule well set forth by the aid of illustrations. As an example of the latter, I may refer to the excellent woodcuts of the skull of Tritylodon from the Trias of South Africa, and of various lower jaws illustrating the section on Mesozoic Mammalia; but additional figures of this most important and little known series of forms would have been welcome, and one reads with unfeigned disappointment the declaration that "it would be beyond the scope of the present work to describe in detail, or even to mention the names of, all the members of this group."

There are one or two points of general interest in the earlier chapters to which I may briefly call attention.

The view originally formulated by Huxley, that in looking among Vertebrates for the progenitors of the Mammalia we must pass over all known forms of birds and reptiles and go right down to the Amphibia, is maintained by the authors, whilst reconciling this conclusion with Prof. Cope's important observations on the remarkable resemblances which obtain between the extinct reptiles known as Theromorpha (Theriodontia, Pelycosauria) and the Monotreme Mammals. Recent observations have shown such an intimate connection between the South African Theromorpha and the Labyrinthodont Amphibians that there can, our authors maintain, be no hesitation in regarding the one group as the direct descendant of the other, and "we may probably regard the Mammalia as having originated from the same ancestral stock at the time the Amphibian type was passing into the Reptilian."

In reference to classification, the authors observe that it is a simple matter to indicate natural groups, such as orders and sub-orders, among existing Mammals, but when we pass to the extinct world all is changed. New forms are discovered which cannot be placed within any of the existing divisions. "Our present divisions and terminology are," say Prof. Flower and Mr. Lydekker, "no longer sufficient for the purpose [of a classification which shall embrace extinct forms]; and some other method will have to be invented to show the complex relationships existing between different animal forms when viewed as a whole." Apparently the authors mean, by the last five words of this sentence, "when all are viewed together." The necessity for drawing up lists and catalogues in a linear series is deplored, but unhappily no attempt is made by the authors to grapple with the difficulty. A classification of the Mammalia in a linear series is given as far as families; and the names of groups containing only extinct forms are printed in special black type. I should have been very glad to see some attempt to set forth in the form of genealogical trees the senior author's views on the genetic relationships of this confessedly artificial linear series. I cannot admit that the division of the Mammalia into three groups—Prototheria, Metatheria, and Eutheria, or, as De Blainville called them, Ornithodelphia, Didelphia, and Monodelphia—expresses a natural fact, if these three groups are regarded as equipollent, and as succeeding one another as three "grades" of evolution. It is not difficult to come nearer to an expression of actual genealogical relations than this. It appears preferable to divide the Mammalia primarily into two grades: (A.) the Monotrema, and (B.) the Ditrema; only so do we give expression to the wide gap by which the archaic characteristics of the Monotremes separate them from all other Mammals. Then we can divide the Ditrema—not into two successive *grades* of structure—but into two diverging *branches*, viz. Branch *a*. Marsupialia, and Branch *b*. Placentalia. Of the Placentalia our authors say that their affinities with one another are so complex that it is impossible to arrange them serially with any regard to natural affinities. They might, however, it seems to me, embody their own conclusions in classificatory form, and divide the Placentalia into four diverging sub-branches, the chief being (*a*) the Typidentata, the three others being (*b*) the Edentata, (*c*) the Cetacea, and (*d*) the Sirenia. The group which I call Typidentata our authors actually define, though they do not name it and use it as would surely be convenient. They say, "The remaining Eutherian Mammals [*i.e.* Placentals after exclusion of Edentata, Cetacea, and Sirenia] are clearly united by the characters of their teeth, being all heterodont and diphyodont with their dental system reducible to a common formula." I have for many years made use in my lectures of the classification of Mammalia above indicated which may be summarized thus:—

Class MAMMALIA.

Grade A. MONOTREMA.
Grade B. DITREMA.

Branch *a*. Marsupialia.
  Sub-br. *a*. Polyprotodontia.
  Sub-br. *b*. Diprotodontia.
Branch *b*. Placentalia.
  Sub-br Sirenia.
  Sub-br. *b*. Edentata.
  Sub-br. *a*. Typidentata.
  Sub-br. *d*. Cetacea.

No doubt it is difficult, even with the use of the additional terms "grade," "branch," and "sub-branch," to set forth the relations to one another of the known orders and sub-orders of Typidentata; but the attempt must be made, and there are materials in the present work for gathering some indications of the form which such a tentative pedigree would take had the authors gone so far as to formulate it.

In the chapter on geographical distribution, the six zoological regions of the globe proposed by Dr. Sclater in 1857 are accepted. But here, as in regard to the treatment of morphological groups, it seems that a primary grouping of the divisions recognized might with advantage be introduced, which would give a truer expression of the historic relations of existing land surfaces than that adopted. Reference is made to the proposed elevation of New Zealand into a primary region, but would not the truth be more nearly expressed by separating New Zealand and the rest of the world first of all, as Atheriogæa and Theriogæa? Should not the Australian region next be separated from the rest of Theriogæa? Theriogæa would then be divided into the Terra Marsupialium and the Terra Placentalium (without prejudice to the recognition of the occurrence of a limited number of Marsupials in the latter). The Terra Placentalium includes the five regions called by Sclater Palæarctic, Nearctic, Neotropical, Ethiopian, and Indian. The authors of the present work mention Dr. Heilprin's opinion that the Palæarctic and Nearctic regions should be united and called the Holarctic region. But they do not adopt this opinion, nor refer to Huxley's proposal to term this same area Arctogæa, and his suggestive speculations as to the successive connections of the three great peninsulas (as they are at present)—the Neotropical, the Ethiopian, and the Indian—with this northern land surface.

I have ventured to cite one or two instances in which the methods of classification adopted in the "Study of Mammalia" appear to be open to improvement. I trust that I may without offence express a doubt as to what precisely is the meaning of the last part of the following passage:—

"The researches of palæontologists, founded upon studies of casts of the interior of the cranial cavity of extinct forms, have shown that, in many natural groups of Mammals, if not in all, the brain has increased in size and also in complexity of surface foldings with the advance of time, indicating in this, as in so many other respects, a gradual progress from a lower to a higher type of development."

I confess that I do not understand what this "lower" and "higher type of development" refer to. The remarkable thing about the small brains of extinct Ungulata is that, whilst they differ enormously in relative size and in the low development of other features from the brains of living Ungulates, their possessors exhibited no corresponding difference of skeletal structure; so that it appears that the brain has had an independent evolution, advancing in size and complexity from the initial phase of the primitive Ungulate far further than has the general body-structure. The gap in respect of brain between man and the highest apes, accompanied as it is by mere trivial differences of bodily structure, appears to be a less marked case of the same general phenomenon. We may say that the brain in the one case is in a lower and in the other in a higher stage of development; but whether the authors mean this merely, or that the whole animal has passed "from a lower to a higher type of development," and to what kind of morphological doctrine that phraseology belongs, are matters which do not immediately explain themselves.

The only way to write of so large, so comprehensive, and so authoritative a work as the present, is to point out a few matters for discussion which a rapid review of its pages suggests. Such indications of topics on which one would like to know more from the authors of a book of this kind are not fault-findings, but samples of the interest which it awakens in a sympathetic reader.

E. RAY LANKESTER.

FORTY YEARS IN A MOORLAND PARISH.

Forty Years in a Moorland Parish. By the Rev. J. C. Atkinson, D.C.L. (London: Macmillan and Co., 1891.)

THE moorland parish of which Dr. Atkinson writes is the parish of Danby, which lies among the Cleveland Hills, some miles inland from Whitby. Here he has worked as a clergyman for forty-five years. To a man of narrow sympathies and little intellectual curiosity the position might have been trying enough; but in the life of the people, in the aspects of Nature, and in local problems appealing to the antiquary and the historian, Dr. Atkinson has found sources of interest which have never lost their charm. In the present volume he records some reminiscences of the pursuits which have occupied him, and of the impressions which have been made upon him, during all these years; and a very fascinating record it is. He not only has powers of keen and accurate observation, but carries on his researches in a thoroughly scientific spirit; and he is a master of the difficult art of stating problems in a manner that secures attention while they are being gradually solved. His immediate subject is Danby; but if the author had never raised his eyes to look further afield, his readers might soon have felt that he had told them about as much as they wished to know. Facts relating to a particular locality can never be really understood unless they are brought into connection with kindred facts in other parts of the world. This is constantly borne in mind by Dr. Atkinson, and his ample learning enables him to apply the principle in many different ways; so that, when he is talking about Danby, he is often talking at the same time about wide regions of the British Islands, and even about stages of culture through which the greater part of the human race has passed.

One of the most interesting of the sections into which the book is divided is the one headed "Antiquarian." In Danby, as in Cleveland generally, there are many prehistoric burial-mounds, and a large number of these he has carefully excavated. The only traces of bronze he has discovered are "a few mouldering fragments of very thin plate, found with the unprotected bones of a cremated body, and not sufficient to fill a very small pill-box half an inch in diameter." Nevertheless, the contents of the larger "houes" prove conclusively that they belong to the Bronze Age; and Dr. Atkinson is of opinion that they date from the later part of the period. He has found many vases of the Bronze Age type, some jet beads, two polished axe-hammers, various bone pins, arrowheads and other objects of flint; and by far the larger proportion of these treasures may now be studied, along with similar treasures recovered elsewhere, in the British Museum. Dr. Atkinson tells with great spirit the story of the more memorable of his explorations; and he has much that is amusing to say about the wonder excited among his rustic neighbours by what seem to them his mysterious proceedings, and about the interest aroused in the minds of those whom he has from time to time induced to help him. Across the ridges between which lie the dales of the district are ancient earthworks, all of which "are defensive against attack from the south, and in no other direction whatever." Of these dykes, which seem to be of the same period as the burial-mounds, Dr. Atkinson gives a full and lucid account, and he offers some suggestive hints as to their relation to other old fortifications in the neighbourhood. He has also an excellent chapter on various pits which have often been described as the remains of "British settlements." There can be little doubt, as he shows, that in reality these pits are the remains of early mining excavations.

Another valuable part of the book is devoted to folklore. The belief in witches has not even yet wholly died out in Cleveland; and forty years ago it was still a more or less potent factor in the lives of the people. The author gives some curious instances of the power formerly attributed to witches, and of the means by which their devices were supposed to be thwarted by the "wise men" of the district. He suggests that witches may not always have been mere impostors, but that in some cases they may have been able to exercise the kind of influence to which the phenomena of hypnotism are believed to be due. Even more interesting than the traces of faith in witchcraft are the survivals of "fairy," "dwarf," and "Hob" notions. According to a tale told to Dr. Atkinson by an old woman, there was a farm in Glaisdale where Hob, so long as he was not spied upon, did much excellent work at night. At last some one was curious enough to watch him, and it was thought he would be all the better for "something to hap hissel' wiv." Accordingly a coarse shirt, with a belt or girdle to confine it round his middle, was made for him, and left in the barn where he worked. When he found the gift, Hob broke out in the following couplet:—

"Gin Hob mun hae nowght but a hardin' hamp,
He'll coom nae mair, nowther to berry nor stamp."

Dr. Atkinson was delighted with this couplet, for it preserves three words which had become obsolete forty years ago, and two of which—"berry" and "hamp"—had no actual meaning to the speaker. "Stamp" was the word for "the action of knocking off the awns of the barley previously to threshing it, according to the old practice." "Berry," meaning to thresh, he had been "looking and inquiring for, for years, and looking and inquiring in vain." As to "hamp," he had "never had any reason to suppose that it had once been a constituent part of the current Cleveland folk-speech." The hamp was a kind of smock-frock, gathered in about the middle and falling below the knee, and was at one time the characteristic garment of the English peasant. The word "seems to be clearly Old Danish in form and origin."

There are several chapters which will give pleasure to students of geology and ornithology; and in his notes on weddings, burials, the harvest-home, and holy wells, the author displays much ingenuity in detecting survivals of what were in past times wide-spread customs. In the interpretation of old historical documents, and in the purely descriptive parts of the book, he is equally successful. Some readers, finding so many things to lure them on from the beginning of the work to the end, may be disposed to think that Danby is a very exceptional parish. What is exceptional, however, is not so much the writer's subject as the knowledge and insight which enable him to appreciate, and to make others appreciate, its true interest and significance.

OUR BOOK SHELF.

Anatomy, Physiology, Morphology, and Development of the Blow-fly (Calliphora erythrocephala). Part II. By B. Thompson Lowne, F.R.C.S., F.L.S., &c. (London: R. H. Porter, 1891.)

THE general features of this study in insect anatomy have already been noticed (NATURE, vol. xliii. p. 77). Part II. describes the exoskeleton in considerable detail, and contains many useful and elaborate figures. Plate v. and the accompanying explanations give the author's views upon the morphology of the insect-head. The pre-oral part he regards as developed from three bladder-like swellings, to which correspond three primary divisions of the cephalic nerve-centres. The post-oral part is supposed to arise by the fusion of three jaw-bearing segments. The terminal portion of the proboscis is probably developed, according to Mr. Lowne, from the first, and not from the second pair of maxillæ. The description of the mouth-parts is very full, and the figures are extremely good.

The thoracic skeleton is also minutely described, perhaps over-minutely, seeing that, in our author's words, "a classification of the various sclerites indicative of their morphological significance is not possible with our present knowledge." Other careful descriptions by special students show that it is easy to interpret the complex thoracic structures in a different way from that here adopted.

Excellent figures are given of the legs, feet, and wings, and the description of the foot of the fly is of very special interest. The wing-joint is described with great care and thoroughness, in connection with the mechanics of flight.

Comparisons between insect and vertebrate structures are made with great boldness. One example will probably astonish common-place morphologists. Weismann observed that the femoro-tibial part of the fly's leg forms at first a mere lateral prominence, which is converted by segmentation and constriction into a bent knee, the upper part yielding the coxa and femur, the lower part the tibia. Mr. Lowne confirms this account, and illustrates it by figuring five stages (Fig. 34). Next he compares the lateral prominence to the exopodite of a biramous limb. Then he adopts Dr. Gaskell's suggestion that the limbs of an Arthropod may correspond to the visceral arches of a Vertebrate. In the following sentence we reach the climax. "The double character of the embryonic appendages in the Crustacea, and in the maxillæ of insects, as well as in the thoracic limbs of the rudimentary fly-nymph, is certainly very suggestive of the double character of the pterygomaxillary arch, or even of the hyomandibular in vertebrates."

So much conscientious labour has been bestowed upon this treatise, and it is so useful to the student of insect anatomy, that it is a pity to see the text encumbered with discussions which, to avoid dogmatism, we will merely call extremely hazardous. Would it not be better to bring out such views in another place, and leave the *magnum opus* free of doubtful matter?

When all deductions have been made, the book must be counted a valuble addition to the literature of the subject. L. C. M.

Races and Peoples: Lectures on the Science of Ethnography. By Daniel G. Brinton. (New York: N. D. C. Hodges, 1890. Sold by Kegan Paul, Trench, Trübner, and Co.)

THE lectures of which this book consists were delivered at the Academy of Natural Sciences, Philadelphia, early in 1890. They present a good general view of the leading principles of ethnography, as these are understood by the author. He begins with a discussion of what he calls the physical and psychical elements of ethnography, next treats of the beginnings and subdivisions of races, then takes in order the divisions in which he arranges the various groups of mankind, and finally deals with problems relating to "acclimation," amalgamation, and the influence of civilization on savages, and offers some suggestions as to the destiny of races. The human species seems to him to include five races—the Eurafrican, the Austafrican, the Asian, the American, and insular and littoral peoples. Each of these is subdivided into branches, stocks, and groups; and an effort is made to define the traits which, according to Dr. Brinton, the members of each race have in common. It is not always easy to understand the principle of his classification. The Eurafrican race, for instance, includes the following groups: Libyans, Egyptians, East Africans, Arabians, Abyssinians, Chaldæans, Euskarians, Indo-Germanic or Celtindic peoples, and peoples of the Caucasus. These peoples are all white; and Dr. Brinton thinks we may also say of them, "hair wavy, nose narrow." But the differences by which they are separated from one another are, at least in some cases, so profound, that it is extremely doubtful whether we are warranted in attributing to them a common origin, except in the wide sense in which a common origin is attributed to humanity generally. So long, however, as Dr. Brinton's classification is understood to be merely a convenient way of bringing together great masses of facts, it may be of considerable service to students. The book embodies the results of much careful research, and is written in a clear and vigorous style.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Crystals of Platinum.

SINCE writing a note on this subject to NATURE (vol. xliii. p. 541) I have found that it is by no means requisite to use topaz in order to obtain crystals of platinum from a ribbon of that metal heated by a current. Thus the ribbon may be dusted over with quartz dust, and if the temperature be raised to that at which this is slowly melting (1430° C. about), crystals of platinum gather upon projecting points on the quartz. Doubtless the presence of fluorine will facilitate, as described in my former letter, the volatilization of the platinum, but there is little doubt that at a temperature some 300° below its melting-point (1750°; Violle) there is a slow volatilization of the metal due either to heat pure and simple, or to this in conjunction with the presence of a current as in high vacua.

To put the possibility of chemical action out of the question, I weighed a clean ribbon of pure platinum, 9 centimetres in length, and passed such a current through it, for 30 minutes, as raised it to nearly the melting-point of palladium (1500°; Violle). The first weighing was 0·0700 grammes, the second (after heating) 0·0688, indicating a loss of 1·7 per cent. of its weight.

I find that Prof. A. S. Törnebohm, of Stockholm, has described in a recently-published paper (*Aftryck ur Geol. Fören. i Stockholm Förhandl.*, Bd. 13, Häft 2, 1891) cubical crystals of platinum formed by the action of chlorine gas upon platinum black at a high temperature. The figures illustrating his paper depict crystals similar to those obtained by the present method.

J. JOLY.

Physical Laboratory, Trinity College, Dublin.

Porpoises in the Victoria Nyanza.

IN Dr. Carl Peters's "New Light on Dark Africa," he speaks of "some large gray-bellied porpoises tumbling about" in Lake Victoria Nyanza, "and rollicking in the tepid flood" (see p. 445).

I should be glad to know whether there is any other authority for the occurrence of a Cetacean in this lake. It is possible, but very improbable, as no Cetaceans are known to occur in the Nile, or other African fresh waters, although there has been a report of the Manatee being found in the Shári, which runs into Lake Tchad (see Barth, "Reisen," iii. p. 289), and the Manatee also occurs in the Niger. P. L. SCLATER.

The Zoological Station at Naples.

IT is desirable that the names of any biologists who wish to make use of the British Association Table at the Naples Zoological Station, during the year commencing in September next, should be in the possession of the Committee before the meeting of the British Association at Cardiff.

Intending applicants are therefore requested to send in their names, and a statement of the nature of the work they propose to undertake, before June 30, to me as Secretary to the Committee. W. PERCY SLADEN.

13 Hyde Park Gate, S.W., June 6.

A BRITISH INSTITUTE OF PREVENTIVE MEDICINE.

ON Friday, June 5, Sir Michael Hicks-Beach received in one of the large rooms of the Victoria Hotel, Northumberland Avenue, an unusually numerous and influential deputation on behalf of the British Institute of Preventive Medicine. Sir Michael Hicks-Beach was accompanied by Sir Henry Calcraft, K.C.B., Secretary to the Board of Trade, Mr. Courtenay Boyle, C.B., and Mr. Walter J. Howell.

Among the members of the deputation were the Duke of Westminster, the Earl of Feversham, Sir Frederick Abel, Sir F. Bramwell, Sir John Lubbock, Sir Benjamin

Baker, Dr. Farquharson, M.P., Sir William Thomson, Sir James Bain, Sir Joseph Fayrer, Sir Philip Magnus, Sir Jacob Wilson, Prof. Dewar, Sir Douglas Galton, Sir Archibald Geikie, Sir William Houldsworth, M.P., Sir George Humphry, Mr. Haldane, Q.C., Mr. Seager Hunt, M.P., Sir Guyer Hunter, M.P., Prof. Ray Lankester, Prof. Norman Lockyer, Mr. Blundell Maple, M.P., Sir Lyon Playfair, M.P., Sir Robert Rawlinson, Sir Henry Roscoe, M.P., Sir George Gabriel Stokes, M.P., Prof. Burdon Sanderson, Sir Henry Trueman Wood, Prof. Victor Horsley, Dr. Armand Ruffer, Mr. Priestley, Sir Henry Simpson, and other members of the Royal, the Linnean, and other scientific Societies.

The following letters were read from Prof. Tyndall and Prof. Huxley :—

"*Hind Head, Haslemere, June* 3, 1891.

"MY DEAR SIR JOSEPH,—The battered remnant of four deadly assaults, I am still a prisoner in my bed. Were I a free man, I should deem it a privilege to join your deputation to Sir Michael Hicks-Beach on June 5. I entirely sympathize with the movement.

"Let me here record a small experience of my own. Last summer, while crossing from Dover to Calais on my way to the Alps, I noticed, huddled up in a corner of the steamer, a poor English boy. He seemed lonely and depressed, and I spoke to him. 'Where are you going, my boy?' I asked. 'To Paris,' was the reply. 'And what are you going to do in Paris?' 'Well, sir,' said he, 'I have been badly bitten by a mad dog, and I am now on my way to Mr. Pasteur, who I hope will save my life.'

"The case prompted sad and bitter musings. Here was wealthy England, with the amplest means at her disposal, with some of her ablest men ready to investigate and apply those means, insanely forbidding such investigation, and compelling her children to resort to a foreign country to have themselves rescued from the most horrible of deaths. As I spoke to the lad, the virulent rabic virus was probably already in his blood, and his chance of life depended on the promptness with which Pasteur's vaccine could be introduced to combat and destroy that virus. Every hour lost in the collection of money for the boy's journey and in making arrangements with Pasteur for his reception—every hour lost in his transport from England to France—was so much time given to the virulent virus to pursue its fatal work, and to ruin the chances of the boy's rescue. This is the state of things to which we in England are forced to submit; this is the condition to which we are reduced, through the deference paid by English statesmen to a noisy and an ignorant faction.

"But while the investigation and treatment of hydrophobia confer immortal honour on Pasteur, this malady is but a small item in the array of disorders now demanding investigation. Suspected from time to time by men of genius in the past, the fact that all communicable diseases are due to micro-organisms, which increase and multiply after the manner of living things, has, in the opinion of our first authorities, been now reduced to demonstration. Your proposed institute is to be devoted to the investigation of such organisms—to the study, that is, of the science of bacteriology. In regard to questions of life and health, such an institution is the most pressing need of England at the present hour. A good deal of the weary time which I have been forced to spend in bed during the last six months has been devoted to making myself acquainted with what is being done by the staff of the Hygienic Institute of Berlin, an institute of which the German nation may well be proud. I have occupied myself in drawing up an account of the researches recently carried out in connection with the institute. In regard to our most fatal disorders, these researches will effect a revolution, not only in public knowledge, but also in the thoughts and practice of medical men. It would, in my opinion, be a lamentable mistake on the part of an English statesman to place himself in official antagonism to the eminent and illustrious men who on June 5 will advocate the founding of a similar institute in England.

"It is, I think, fortunate that you have in Sir Michael Hicks-Beach a statesman not likely to fall into the extravagances of sentimentalism. The overwhelming preponderance of English intellect will be represented by the deputation. He may rest assured of it that this preponderance will become more and more conspicuous, until finally the misguided opponents of a true philanthropy will cease to engage the attention, much less enlist the sympathy, of the English people.

"Believe me, dear Sir Joseph, most faithfully yours,

"JOHN TYNDALL.

"Sir Joseph Lister, Bart."

"*Hodeslea, Eastbourne, June* 2, 1891.

"DEAR SIR JOSEPH LISTER,—I am very sorry that I am unable to join your deputation on June 5.

"If I could have been with you, I think I should have asked to be permitted to point out to the President of the Board of Trade that medical science is not excepted from the rule which holds good for other branches of natural knowledge, and that it can be advanced only by reasoning based upon observation and experiment, and constantly controlled by both, especially by the latter.

"Further, that by working in this fashion a marvellous improvement of medical science has been effected during the last half-century, and that the harvest of what Bacon called 'fruits,' which is now waiting for the gatherer, might fully occupy half a dozen such institutes as that in which we are interested.

"Starting from the unquestionable facts that the work we propose to undertake is of supreme public utility, and that the number and extent of the problems of pathology are enormously great in proportion to any existing means of dealing with them, I should have ventured to ask why we should be refused the only privilege we seek—namely, that official recognition by the Board of Trade which will afford the institute security against the possible misuse of its funds in future?

"No doubt, however, all these points will be much more effectually put by yourself and other members of the deputation.

"I am yours very faithfully,

"T. H. HUXLEY.

"Sir Joseph Lister, Bart., F.R.S."

Sir Henry Roscoe, M.P., in introducing the deputation, said that it represented not only the whole body of medical men in this country, but also, without exception, all the scientific elements amongst scientific men, and also a large number of others who were interested from the national point of view in the establishment of an institute of preventive medicine for this country, and for which it was proposed to obtain incorporation under the Board of Trade. He need not go into the question as to the national importance of an institution of this kind. There was no civilized country in Europe, and scarcely anywhere else, in which this subject had not awakened the interest and claimed the attention, not only of the scientific men, but also to a great extent of the Governments of those countries. What they asked was that Sir Michael Hicks-Beach would be good enough to enable them to found and to carry on a British Institute of Preventive Medicine, analogous and of a similar form to those great institutes which existed in France, Germany, Russia, and in a great number of other countries. They were sorry to find that the object which they had in view and the request that they made to Sir Michael had not met altogether with the success which they had hoped. They learnt from the answer which he had given to Major Rasch in the House of Commons that the refusal to grant what they requested was based on objections received by the Board of Trade. They merely asked that the institution should be registered under the Limited Company Act, with the omission of the word "limited," in order to impress the public with the fact that the institute was not established for the purpose of gain, but purely for sanitary and scientific objects. The objections were based upon the fact that a part of the work would include experiments on animals. In reply to this they had the opinion of counsel that the Board of Trade had only to satisfy themselves that the object was charitable, and that the promoters were persons whose position was a sufficient guarantee of the high character of the proposed institute.

Sir Joseph Lister said the object of their deputation was to request Sir Michael Hicks-Beach to reconsider his decision, and to grant the licence under the Board of Trade which was really, as it would seem, almost essential to the prosperity, if not indeed to the very existence, of the institute. It was essential, in order that they might hold money in trust, that they should be incorporated. They had been promised a large sum of money, the receipt of which would be essentially dependent upon their incorporation, and if they were incorporated as a limited liability company they would not be able to appeal to the public for funds with any success. In the first place, their institution would have a mercantile character, which would tend to repel subscribers; and they had the opinion of counsel that under such circumstances it would be in the power of the subscribers at any time to agree to have the institute wound up and the funds divided amongst themselves. To appeal to the public for subscriptions, therefore, under these conditions would be absolutely hopeless. On the other hand, if the licence were granted there could be inserted by the Board of Trade a condition that the funds of the institute should be used only for scientific and charitable objects, and in that way their position would be perfectly secured. The only practical alternative, if it was still thought right to refuse their request, would be that they should be incorporated by Act of Parliament—a process which would involve very great loss of time and also very serious expense. The importance of the object which they had at heart was one which he thought need hardly be much dwelt upon. Preventive medicine based upon bacteriology was a matter of comparatively recent experience, but it had been making gigantic strides, and every year and almost every week they were learning of new triumphs achieved in the discovery of the essential nature of disease and of the means of preventing such disease. He might be permitted perhaps to refer to one or two illustrations of the value of the work carried on at such institutes both to man and to the lower animals. The work done by M. Pasteur for the rescue of those bitten by mad dogs from the horrible death of rabies was bearing invaluable fruits. It had been estimated that within four years at the Pasteur Institute 12,000 lives had been saved. During the last six years 403 British subjects had been treated, and out of those 403 only seven had died. If they took into account the loss of time involved in making arrangements for going to Paris, and considered also that the essence of M. Pasteur's treatment was to intercept the disease before it arrived at the vital organisms in the brain, they might anticipate a large amount of success if they had the means in this country of having the same treatment carried out. From Germany had come the discovery of what was termed tubercle bacillus—that was to say, the micro-organism which was the essential cause of tubercle, the greatest physical scourge that afflicted the human race. To establish that that bacillus was really the essential cause of this disease in all its diverse forms required a large amount of investigation such as could only be carried on in institutes like that which they desired to see established. That the institute would be of great benefit also with regard to diseases of the lower animals might be seen from the discoveries made as to the cure of anthrax by M. Pasteur, and as to the treatment of another affliction known as "quarter evil" by a scientist of Lyons. Various bacteriological laboratories had been already established in the British Islands, but it was universally allowed that none of those existing was in the least equal to a great institute such as they desired to see established. One proof that such was the case was presented by the fact that our best workers in these subjects had been going continually to Paris or to Berlin for the superior advantages that they could obtain there. He ventured to think that the mass of educated opinion represented by the deputation was surely more deserving of attention than the views of those who, with whatever excellent intentions, had petitioned against their scheme. The truth was that objections were made because the petitioners objected altogether to the performance of experiments upon living animals, and not because they thought that there was already sufficient opportunity for work of this kind. If those petitioners knew how very small was the amount of suffering really inflicted upon the animals in such an institute, and how scrupulous was the care taken to avoid all needless pain, they would not (at least, the great majority of them would not) have made the opposition that they had made. He even doubted whether the question of their being likely to perform experiments upon living animals was one which the Board of Trade had any fair reason to occupy itself with. The licensing of places for the performance of such experiments, and the licensing of individual experimenters had always rested with the Home Secretary. Foreign institutions such as that which they desired to see established had been largely endowed by the State, and he did not relinquish the hope that our Government might at some future time see its way to give them substantial aid. But, however that might be, they ventured to hope that no department of this Government would oppose any unnecessary obstacle to an enterprise which had for its sole object the welfare of humanity, the health of mankind and the lower animals, and the general progress of the public weal.

Sir Lyon Playfair, M.P., said that experiments on living animals had been sanctioned by Parliament, which had intrusted the Home Secretary to make suitable restrictions for the carrying out of the operations. The proposed institute was promoted differently from those in foreign countries, which were being founded by the State, and the deputation only asked to be allowed to associate for a purpose recognized by Parliament, and with such restrictions as Sir Michael Hicks-Beach or the Home Secretary thought proper to impose.

Prof. Dewar spoke of the importance of the proposed institute from a chemical point of view, and Dr. Ray Lankester and Sir James Crichton Browne also spoke.

Sir M. Hicks-Beach, in reply, said:—I hope that it is not through any fault of mine that those who have arranged for this deputation have not come to me in the ordinary numbers of a deputation, but have thought it necessary for their object to summon from different parts of the country so very large a number of gentlemen who are very actively engaged, and whose time must be very valuable, not only to themselves, but also to the public. I am not disposed to be influenced in any matter by the mere numbers of a deputation. It would be perfectly possible for you and for those who differ from you on the other side to fill a very much larger room than this. I think the deputations should be weighed rather than counted, and if half-a-dozen of those who are now present had come to me saying what has been said to-day, and authorized to speak on behalf of all of you, I can assure you that I should have attached as much weight to their arguments as I can do now. But, of course, I accept your presence here as a strong testimony to the great interest that you feel in this subject. I am sorry to confess to have differed from so many gentlemen of such eminence as those who have supported this movement, and to have found myself unable to grant the application of the British Institute of Preventive Medicine for permission to register the Association without the addition of the word "limited." It is only due to you that I should explain, as shortly as I can the reasons which induce me to arrive at that decision. Now, the section of the Act of 1867, under which you ask me to act, lays down two preliminary requirements which must be proved to the satisfaction of the Board of Trade—first, that the Association shall be formed for one of several purposes, such as, for instance, that of promoting science, or some other useful object; secondly, that the profits or income will be applied to promote the objects of the Association, and that the payment of dividends will be prohibited. Now, I will assume that you have complied with both these requirements; I say nothing to the contrary. But the proof of such compliance does not, in my opinion, compel the Board of Trade to act on the section. Something has been said to-day to the effect that you have obtained counsel's opinion that it does compel the Board of Trade so to act. I have taken another view—I admit without legal advice. If you will place before me the opinion upon which your view is based, of course I shall very carefully consider it, and myself obtain legal advice upon that point, because I view it as an important point, as you will see from what I am going to say. I have considered, as I said, that the section of the Act only empowers the Board of Trade to act, and leaves it to the Board of Trade to decide whether the licence shall be granted or not; and if granted, whether any conditions or regulations should be imposed and inserted in the memorandum and articles of association. It therefore seems to me that the Board of Trade could hardly grant such a licence without expressing approval, by the mere fact of the grant, of the Association to which it is granted. In your case I think I have no right to express such an approval, because, if I rightly interpret Clause 3*a* of your memorandum, I understand—and I also gathered from what has been said to-day—"that experiments on living animals calculated to give pain," to quote the words of the Act of Parliament, are included among your objects; in one word, that vivisection would be part of your work. Now, this is a subject which the Legislature by the Cruelty to Animals Act, 1876, has placed under the control, not of the Board of Trade, but of the Home Office. By that Act, as you know, vivisection is made illegal except by licence from the Home Office, and under the most stringent regulations, including inspection by inspectors of the Home Office. I assume that when you had established this institution, supposing my licence were granted, an application would be made to the

Home Office for a licence or licences for vivisection on the premises of the institute for some one or more of its members. It seems to me that the Home Secretary would have fair ground to complain of my action, if in a matter of such admitted difficulty, rousing as it does the strongest feelings of both sides, I did anything which would enable you to go before him, to whom Parliament has intrusted this subject, with the stamp of approval as it were from another Government department which has nothing to do with the subject at all. Now, I hope I have put that shortly and plainly. What are your alternatives? You have said something to me on this subject to-day. You can, of course, if you choose, remove from your objects anything which could bring you within the Cruelty to Animals Act, 1876. If you did that, my objections would be entirely removed. You could, if you chose, form yourselves as a Society, vesting your property in trustees; associate yourselves under the Companies Act as a limited company, inserting a proviso that you should pay no dividends. Now, I should like to have before me the reasons in writing which have been urged to-day why none of these courses would meet your views. I can only say in conclusion that I have endeavoured to put to you the difficulty which I feel; that I will carefully consider what has been said to-day; and any documents which the promoters of the Association wish to place before me to enforce the views which have been expressed I shall be glad to receive.

Sir John Lubbock, in moving a vote of thanks to Sir Michael Hicks-Beach, said that Sir Henry Roscoe had authorized him to say that the further information which had been asked for should be furnished to the Board of Trade. Vivisection was after all a very small part of the question before them, unless, indeed, vivisection was to be understood as applying to the bacteria. He would venture to remind Sir Michael that although Acts of Parliament might prevent them from destroying the bacteria, they could not prevent the bacteria from destroying human beings, and it seemed almost a significant fact that no members of the community, as he knew to his own cost, had suffered more from them than members of the House of Commons. He had no reason to suppose that bacteria suffered at all, though human beings suffered very much from the bacteria. The bacteria were now experimenting upon them, and all that they asked was that they should be allowed to defend themselves from the bacteria. Something had been said about agriculture, and he believed that such an institute as this would add much to the prosperity of agriculture and probably of manufactures and of commerce. As regarded the technical points which had compelled the right hon. gentleman to adopt the course which he had taken, he thought if Sir Michael went into the matter he would find at least two precedents in which an opposite line had been taken in cases where vivisection was practised.

The President—I ought to mention that any of the precedents which have been mentioned I should like to have placed before me.

The deputation then withdrew.

EARTH-CURRENTS AND THE ELECTRIC RAILWAY.

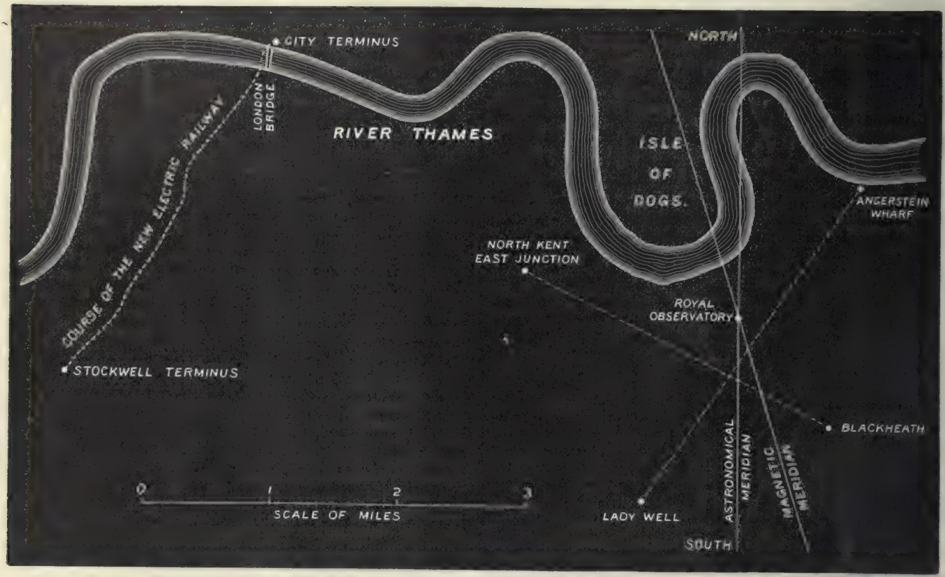
A WELL-MARKED case of interference with the earth-currents recorded at the Royal Observatory, Greenwich, due apparently to the working of the new Electric Railway, having recently been experienced, of which some account might prove to be interesting to electricians, the Astronomer-Royal has kindly allowed me to communicate for publication in NATURE some particulars in regard thereto.

It is known that for many years past a continuous photographic register of earth-currents has been maintained at the Royal Observatory. There are two circuits. For one circuit the earth-plates are at Angerstein Wharf (A.W.), on the southern bank of the River Thames, near to Charlton, and at Lady Well, Lewisham (L.W.); for the other circuit the earth-plates are on Blackheath (B.), at the south end of the North Kent Railway tunnel, and at the North Kent East Junction (N.K.E.J.) of the South-Eastern Railway, the junction of the North Kent and Greenwich lines. The earth connection is in each case made by an independent copper plate; these plates are used only for the earth-current lines, no other wires being attached thereto. From the A.W. earth-plate the wire passes by the South-Eastern Railway lines to the Greenwich Station, thence underground to the Royal Observatory recording apparatus, returning underground to the Greenwich Station, and thence by the railway to the earth-plate at L.W. Similarly for the Blackheath-North Kent East Junction circuit. The direct distance between the A.W. and L.W. earth-plates is 3 miles, and between the B. and N.K.E.J. earth-plates about 2½ miles. The azimuth of the A.W.-L.W. line, reckoning from magnetic north towards east, is 50°; the azimuth of the B.-N.K.E.J. line, reckoning from magnetic north towards west, is 46°. Registration is effected in the usual way. In each circuit there is a horizontal galvanometer the needle of which carries a small mirror; on this the light from a fixed gas-lamp falls, and, reflected therefrom, finally reaches the revolving cylinder as a small spot of light.

Some few particulars concerning earth-current motions generally may perhaps be given. It has been found that all cases of disturbance of the magnets are accompanied by earth-currents, more or less powerful as the magnetic disturbance is more or less pronounced. The correspondence is most complete. No sudden marked motion of the magnets ever occurs without corresponding active earth-currents, as may be seen by the plates (copies of the various registers) given in the several Greenwich volumes since the year 1882. On days on which the magnets are free from disturbance, and show only the ordinary diurnal change, earth-currents are very feeble.

Before speaking of the recent case of interference, we may devote a few words to the description of a previous case in which the interference was much less marked in character, although, with some intermissions, otherwise very persistent. Some five years or more ago it was remarked, in the A.W.-L.W. register, that at one part of the day a slight dislocation of the trace occurred, in no case indicating a change of potential of more than 0·1 volt, frequently much less: after some hours the trace as suddenly returned to its normal position. This was not discernible every day, but still frequently, and still continues. Nothing has been perceived in the other circuit. On examining the A.W.-L.W. records for a number of months, it appears that at all parts of the year the dislocation occurred some three-quarters of an hour after sunset, and the return to normal position at about the same interval before sunrise. The cause of the interference has not been traced, although it has been conjectured that in some way it may be connected with electric lighting in the vicinity of the A.W. earth-plate.

We now come to the recent much more serious case of interference. Towards the end of last year anomalous appearances began to be observed in both of the earth-current registers, not continuously but in a somewhat irregular manner. Now, however, for some months past, these new interruptions have settled down into a regular order. What is perceived is that the interference in question, causing a continuous vibration of the registering needles, commences shortly before 7h. in the morning, goes on all through the day, terminating shortly after 11h. in the evening. This went on for several months on week-days only, ceasing on Sundays, nothing being seen after 11h. p.m. on Saturday, until 7h. a.m. on Monday. But on Sunday, April 5, and on every succeeding Sunday to the present time, the interference has been experienced also on a portion of the Sunday, commencing at about 1h. p.m., and terminating usually at 10h. p.m. or shortly afterwards. Various experiments were made with the view of discovering the cause of these anomalous appearances, but without definite result. Quite recently, Mr. Leonard, the telegraphic superintendent of the South-Eastern Railway, to whom the Observatory is much indebted for considerable assistance in many matters connected with the earth-current work, was led to suggest that the exceptional appearances were most probably due to the influence of the new Electric Railway, three miles in length, and having terminal stations in the City and at Stockwell. A comparison being made between the observed times of interference with the earth-current registers, and the published times of running of the Electric Railway trains, it was found that these were simultaneous. Further, in the early part of the year, during the period in which the earth-current registers were free from interference on Sunday, there were correspondingly no Sunday trains. But on Sunday, April 5, it appears that trains commenced to run on Sunday afternoon, the same day that Sunday interference was first noticed at Greenwich, and these Sunday afternoon trains have been since continued. The whole matter is better seen in the annexed tabular statement:—



Times of interference with earth-current registers at the Royal Observatory, Greenwich.	Train service on Electric Railway.	
On week days.	On week days.	
From shortly before 7 a.m. until shortly after 11 p.m.	First train from Stockwell	6.40 a.m.
	,, ,, City ...	6.50 a.m.
	Last train from Stockwell	10.46 p.m.
	,, ,, City ...	10.58 p.m.
On Sundays, commencing April 5.	On Sundays, commencing April 5.	
From about 1 p.m. until 10 p.m. or shortly afterwards.	First train from Stockwell	1.0 p.m.
	,, ,, City ...	1.5 p.m.
	Last train from Stockwell	9.30 p.m.
	,, ,, City ...	9.30 p.m.

The line of the Electric Railway runs from about north-east to south-west magnetic, or more accurately the azimuth of the line, reckoning from magnetic north towards east, is about 50°. The nearest earth-plate to the railway is the N.K.E.J. plate, which is distant from the railway, in a perpendicular direction from it, about 2½ miles.

The correspondence so far as the comparison goes is complete. During the periods of interference the registering needles at the Observatory are in continual vibration. Whether the impulses are in one direction only or in both directions, and what is their frequency, cannot be readily determined from the registers. Eye observation of the needles may perhaps reveal something to us on these points. The abnormal excursions of the needles indicate a change of potential varying from a small fraction of a volt to perhaps the one-third of a volt or more. When any marked earth-current action arises, the interference becomes in some degree neutralized, and less marked in character.

It was found in the course of previous experiments, that when, instead of employing the complete A.W.-L.W. circuit, the A.W. branch only was allowed to register, by putting the wire to earth at Greenwich, the amplitude of vibration of the needle was not perceptibly changed, neither was it changed when the L.W. branch only was allowed to register. Correspondingly, when the B. branch alone of the B.-N.K.E.J. circuit was allowed to register, the vibration was much diminished, whilst with the N.K.E.J. branch alone registering it was much increased.

William Ellis.

THE ANNUAL VISITATION OF THE ROYAL OBSERVATORY.

THE Report presented by the Astronomer-Royal this year is of more than usual interest. The first part deals with proposed new buildings.

It has been decided that the museum or storehouse for portable instruments and apparatus should be built so as to form the central octagon of a future cruciform structure in the South Ground, which would accommodate the physical branch of the Observatory, and would carry the Lassell equatorial and dome at such a height above the ground that the neighbouring trees would not interfere with the effective use of the instrument. The building for the Museum was commenced at the beginning of March. In consequence of a recent decision of the Admiralty to largely increase the number of chronometers and deck watches for the Navy, additional accommodation for chronometers is required immediately, the space in the present chronometer room being insufficient even for existing requirements.

In other directions the difficulty of providing in the existing Observatory buildings for the accommodation of the increasing staff and of the accumulating material is severely felt, and it is very desirable that the pressure on the space available should now be relieved by means of a comprehensive scheme, which would supply a suitable fireproof brick building to replace the wooden sheds and huts which now disfigure the Observatory grounds, and to provide for the expansion which has taken place in late years, and which may be expected to continue in the future.

To provide for the efficient working of the 28-inch refractor about to be mounted on the south-east equatorial, the Admiralty have authorized the construction of a new iron-framed dome, 36 feet in diameter, to be erected on the south-east tower in place of the existing wooden drum, which, as mentioned in the last Report, has been so much strained in the course of thirty years, that there is great difficulty in turning it. An attempt was made to render the existing dome more serviceable by bolting the framework together more thoroughly, and by substituting properly turned spheres for the cannon-balls, but though the dome is not now liable to stick fast as formerly, it is still very difficult to turn, and cannot be considered serviceable. The new 36-foot dome, which is being constructed by Messrs. T. Cooke and Sons, is of peculiar form, adapted to the conditions of the case, the diameter being greater than that of the tower on which it is erected.

A photographic telescope with 9-inch object-glass by Grubb, and a prism of 9 inches diameter by Hilger, have been generously presented to the Royal Observatory by Sir Henry Thompson. The telescope has been mounted on the Lassell telescope as a photoheliograph, to give 8-inch pictures of the sun; a camera with Dallmeyer doublet (from photoheliograph No. 4), and an exposing shutter, specially designed to give very short exposures, being attached to it.

Six more electric hand lamps and an Ampère gauge (Sir W. Thomson's) have been purchased.

In view of the advantage resulting from the use of electric lighting for the photographic equatorial and for other instruments, the Astronomer-Royal considers it very desirable that an electric light installation should be provided for the Observatory, so that this method of lighting, which is specially adapted to the requirements of an observatory, may be applied to the instruments generally. The system now in use, of charging storage cells from primary batteries, is necessarily extravagant, and it does not admit of the desired extension.

With regard to the work done, the following statement shows the number of observations made with the transit-circle in the year ending May 10, 1891:—

Transits, the separate limbs being counted as separate observations	6036
Determinations of collimation error	307
Determinations of level error	390
Circle observations	5789
Determinations of nadir point (included in the number of circle observations	387
Reflection observations of stars (similarly included)	593

For determining the variation of personal equation with the magnitude of the star, 324 transits, not included in the above, have been observed. The apparent magnitudes of the stars are altered by placing a wire gauze screen in front of the object-glass of the telescope, and part of a transit is observed with clear aperture, part with obscured. The comparison of the two results gives the difference of personal equation for a definite change of magnitude. It appears that all the four regular observers record the times of faint stars later than bright, the difference per magnitude being about $0^{s}\cdot01$.

Altazimuth.—The total number of observations made in the year ending May 10, 1891, is as follows:—

Azimuths of the moon and stars	253
Azimuths of Mark I.	123
Azimuths of Mark II.	193
Zenith distances of the moon	118
Zenith distances of Mark I.	124
Zenith distances of Mark II.	188

Reflex Zenith Tube.—Since the date of the last Report, 14 double observations of γ Draconis have been made and completely reduced to the end of 1890. M. Lœwy's recent work seems to show that the determination of the constant of aberration with this instrument is more trustworthy than had been supposed; though the circumstance that the observations give a negative parallax for γ Draconis suggests that there is some unexplained source of error.

Sir H. Grubb reports that the object-glass and tube of the 28-inch refractor are now practically ready for mounting; but the Astronomer-Royal proposes to delay this operation until the completion of the new dome on the south-east tower mentioned in the first section of this Report.

Work with the 13-inch photographic refractor was seriously delayed by the accident to the driving-clock, and, later, by the illness of Mr. Criswick; but 81 stellar photographs have been taken, all of which must be regarded as more or less experimental. Ferrous oxalate development was used throughout, and all the plates were photographically impressed with the *réseau* kindly supplied by Prof. Vogel. The exposures have varied from a few seconds to about an hour; and trails have been taken both on the equator and near the pole to test the adjustment for orientation. Several different kinds of plates have been used, including Cramer, Seed, Paget, Star, Mawson and Swan, and Ilford; and on the whole the choice seems to lie between the Star and the Ilford plates.

Spectroscopic and Photographic Observations.—For determination of motions of approach or recession of stars, 286 measures have been made of the displacement of the F line in the spectra of 31 stars, and 14 of the *b* line in the spectra of 6 stars, besides comparisons with the spectra of Mars, the moon, the sun, or the sky, as a check on the general accuracy of the results. The series of observations with the 12¾-inch refractor is now practically completed, and the results are under discussion. An examination of those for the 21 stars most frequently observed shows that there is a systematic error depending on the hour angle, thus necessitating a correction for the position of the spectroscope at the observation.

In the year ending May 10, 1891, photographs of the sun have been taken at Greenwich on 224 days, and of these, 483 have been selected for preservation, besides 18 photographs with double images of the sun for determination of zero of position.

Magnetic Observations.—The following are the principal results for the magnetic elements for 1890:—

Mean declination ...	17° 28′·6 W.
Mean horizontal force	3·9546 (in British units). 1·8234 (in metric units).
Mean dip	67° 21′ 19″ (by 9-inch needles). 67 22 53 (by 6-inch needles). 67 24 24 (by 3-inch needles).

Meteorological Observations.—The continuous registration of meteorological phenomena has been maintained without interruption, except for four days in February when the old thermograph and shed in the magnetic ground were dismounted, and the new thermograph and shed were transferred from the South Ground to the position formerly occupied by the old instrument, to make way for the new buildings in the South Ground.

The mean temperature of the year 1890 was 48°·6, being 0°·6 below the average of the preceding 49 years. The highest air temperature in the shade was 82°·8 on August 5, and the lowest 13°·1 on March 4. This latter is the lowest temperature registered in March since 1841, being the same us that recorded on March 13, 1845. The mean monthly temperature in 1890 was below the average in all months excepting January, March, May, and September. In December it was below the average by 10°·0, and in January above by 5°·2.

The mean daily motion of the air in 1890 was 272 miles, being 10 miles below the average of the preceding 23 years. The greatest daily motion was 837 miles on January 26, and the least 32 miles on August 6. The greatest pressure registered was 14·5 pounds on the square foot on January 26.

During the year 1890 Osler's anemometer showed an excess of about three revolutions of the vane in the positive direction N., E., S., W., N., excluding the turnings which are evidently accidental.

The number of hours of bright sunshine recorded during 1890 by the Campbell-Stokes sunshine instrument was 1255, which is about 35 hours below the average of the preceding 13 years, after making allowance for difference of the indications with the Campbell and Campbell-Stokes instruments respectively. The aggregate number of hours during which the sun was above the horizon was 4454, so that the mean proportion of sunshine for the year was 0·282, constant sunshine being represented by 1.

The rainfall in 1890 was 21·9 inches, being 2·7 inches below the average of the preceding 49 years.

The winter of 1890–91 was remarkable for a long period of exceptionally cold weather which commenced on November 25, 1890. From this day till January 22 the mean temperature on every day except January 13 was below the average. The temperature was continuously below 32° on November 27, 28, December 10 to 19, 22, 23, 25, 28 to 30, January 2, 6 to 8, 10, 11, 17 to 19. The greatest defects from the average of 20 years were on November 28 (– 19°·1), December 22 (– 20°·7), and January 10 (– 19°·3). The lowest temperatures recorded during the three months were 18°·3 on November 28, 13°·4 on December 22, and 12°·0 on January 10. The mean temperature of December 1890 was 29°·8, or 10°·0 below the average of the preceding 49 years, the coldest December on record since 1841 previous to 1890 being that of 1879, whose mean temperature was 32°·4. In this same month, December 1890, only 2^{h}·4 of sunshine were recorded.

Chronometers, Time Signals, and Longitude Operations.—The number of chronometers and deck watches now being tested at the Observatory is 169 (113 box chronometers, 20 pocket chronometers, and 36 deck watches). The annual competitive trial of chronometers commences on July 4, and the trial of deck watches on October 24.

The time-balls at Greenwich, Deal, and Devonport are next referred to.

The reductions for the longitude Paris–Greenwich are now completed and ready for publication. In reference to the discrepancy between the results of the French and English observers, mentioned in the last Report, Commandant Defforges visited Greenwich in June 1890, and went carefully through the reductions with Mr. Turner and Mr. Lewis. No mistake was found in the work, but several questions of some importance were raised. The results of the discussion and of subsequent correspondence are summed up in two papers by Mr. Turner and one by Colonel Bassot and Commandant Defforges, in the *Monthly Notices of the Royal Astronomical Society*, vol. li. pp. 155, 407, and 413 respectively. As the matter now stands, the English definitive result for the difference of longitude between the Greenwich transit-circle and Cassini's meridian is 9^{m} 20^{s}·86, while the French result (not yet published) is about 0^{s}·15 greater, a discordance which, though only about half of that found in the preliminary discussion, is still so large, that there seems to be no alternative but to repeat the work with special precautions suggested by the experience gained.

The proposal to determine the longitude of Montreal as the base station for the Geodetic Survey having been sanctioned by the Admiralty last December, arrangements have been made in concert with Prof. McLeod, of the McGill College Observatory, Montreal, for a determination of the longitudes Montreal–Canso–Waterville–Greenwich, the termini of the cable, Canso and Waterville, being occupied as longitude and not merely as transmitting stations, a course which seems advisable in view of the great geodetic importance of these points. The necessary funds have been voted, and the Commercial Cable Company have generously granted the use of their cable.

The determination of the longitude of Washington has been deferred for the present.

During the past year, Lieutenants Heming, Monro, and Smyth, R.N., and Captain Haynes, R.E., have at various times been instructed in transit-observing. Mr. S. Hirayama, of the Tokio Observatory, was at work for some weeks studying the general organization of the Observatory.

THE CLASSIFICATION OF THE TUNICATA IN RELATION TO EVOLUTION.

THE detailed classification of the Tunicata, and especially of the so-called "Compound Ascidians," has usually been found a matter of special difficulty by systematists, and each successive investigator has discovered grounds for modifying in important respects the grouping of genera and families established by his predecessors. A glance at the systems of Giard, Della Valle, von Drasche, and Lahille, all of recent date (*i.e.* post-Darwinian, and since the introduction of modern methods and the recognition of the Tunicata as Chordata), shows the notable want of agreement between competent authorities. There is probably a special reason for this exceptional diversity of opinion, and I believe the cause is to be found in the course of evolution or phylogeny of the group, and especially in the complex relations between the Compound forms and the other Tunicata.

In fact, if the matter be regarded from the point of view of the consistent evolutionist, the special difficulties vanish, the complicated relationships between groups (which can only be represented by dendritic diagrams, or even in some cases by networks) become explicable and natural, the great diversity in value of the assemblages of forms known as "genera" and "species" is simply what would be expected, and the differences between the various classificatory systems (allowing for a few errors which have been corrected by later investigations) can be accounted for, and the conflicting opinions of the authors reconciled. But, on the other hand, if the subject be approached from the standpoint of the pure systematist, whose object is to divide and subdivide into clearly defined groups of approximately equal value, and to recognize only "good" genera and species, nothing but confusion results; it becomes practically impossible to distinguish and arrange naturally the groups of Simple and Compound Ascidians; and some of the most interesting and instructive points, such as the gradation of varieties into species and species into genera, and the individual variations in specific characters, are altogether lost sight of.

These views were expressed partly in my Reports on the *Challenger* Tunicata, but further work since—on some very extensive collections from Australian seas and on the Ascidians of our own coasts—has convinced me that the only rational explanation of the protean forms and labyrinthine inter-relations of the Ascidians is to be found in regarding the group as one in process of evolution, where many of the species, genera, &c., have not yet become markedly differentiated by the elimination of intermediate forms, and where the animals are so much at the mercy of their environment that a special premium is set upon useful characters (if, indeed, there are any "specific" characters which are not useful), and where, consequently, the relations between modification of structure and conditions of existence brought about by the action of natural selection are exceptionally evident. Adopting, then, this view, the following difficult subjects of dispute, and probably others with which I am not concerned at present, can be, I think, satisfactorily explained: (1) the connection of the Simple with the Compound Ascidians, and the classification of the latter; (2) the value of some modifications of the branchial sac; (3) the position of the Polystyelidæ; (4) the relations between the sub-families and genera of the Cynthiidæ; and (5) the numerous "species" of the genus *Botryllus*.

(1) If the attempt is made (as in most classifications) to regard the Compound Ascidians as a group distinct from the Ascidiæ Simplices, and forming either a parallel or a divergent line in regard to the latter, one meets at once with the serious difficulty that the Compound Ascidians show affinities with the Simple at several distinct points. Three investigators approaching the Compound Ascidians after the previous study of certain Simple Ascidians—say, the first fresh from *Ciona*, *Ecteinascidia*, and *Clavelina*, the second from *Perophora*, and the third from *Styela* and *Polycarpa*—could each make out a good case for the view that his new subjects were most closely connected with the genera he had just been working at. The first could demonstrate the undoubted relations, in external form and in structure of branchial sac, between *Clavelina* and *Chondrostachys*, *Colella* and the other Distomidæ; the second might point to the similarity (on which I personally lay no stress) of *Perophora* and the Botryllidæ, in the relations of alimentary canal to branchial sac; and the third could show the close similarity between the Styelinæ and the Compound forms *Synstyela*, *Goodsiria*, and *Chorizocormus* in nearly every detail of internal structure: and all three would be partly right, and therefore unlikely to agree upon any one system of classification.

But when the attempt is made seriously to form a conception of the past history or evolution of the forms in question, it becomes obvious that the Compound Ascidians are not a natural, but an artificial group. That is, they are not the whole surviving descendants of a single group of ancestors, but are polyphyletic in origin, being derived from several distinct lines of ancestry which have arisen independently from different kinds of Simple Ascidians, and have since acquired the common characteristic of being able to reproduce by gemmation so as to form compact colonies in which the members (ascidiozooids) are embedded in a common test or investing mass. We know with as much certainty as we know anything in such phylogenetic inquiries that the ancestral Tunicates were not colonies, and that reproduction by gemmation was not a primitive character. This property has, then, been acquired secondarily by some ancestral Simple Ascidians, and may very possibly have been acquired more than once (though this is not at all necessary for my theory of the polyphyletic origin). It follows from this view (which I have expressed before, but now feel more certain of from recent work), that if we are to retain the group Ascidiæ Compositæ, or Synascidiæ, in our system, we must represent it as linked on to the Ascidiæ Simplices, at three points at least, and we must not attempt to arrange the families and genera in a series diverging from any one of these points alone; or if we do, we need not be surprised when we arrive at obviously unnatural arrangements which are in conflict with the classifications of our fellow-workers.

On the other hand, we might abolish the group Ascidiæ Compositæ altogether as a sub-order of Ascidiaceæ, on the ground that it is not a natural group (*i.e.* a compact set of descendants from a common ancestor—a single branch of the genealogical tree).

But if we adopt this course with the Compound Ascidians, the same argument might be used in connection with other polyphyletic groups throughout the animal kingdom. They should all be broken up, it might be urged, as being artificial assemblages. And that would be a perfectly logical and definite position to take up, and one for which a good deal could be said, but before adopting it zoologists should remember that it involves a loss as well as a gain. If it gives "the system" a certain precision, and an advance of a step or two towards the goal of a completely natural classification, it at the same time destroys the recognition of characteristics which certain forms possess in common. In whatever manner they have been obtained, there is no doubt that Compound Ascidians of the present day possess certain features by which they can be identified as Compound Ascidians, and this fact is surely worthy of recognition in our "system." My own opinion, then, is that the group Ascidiæ Compositæ should still be retained, but that its polyphyletic origin and multiple connection with the Ascidiæ Simplices should be carefully borne in mind when drawing up any scheme of classification, or discussing affinities.

(2) Some of the ideas noted above, and others to be discussed below, took definite form lately in reading a recently published memoir by M. Fernand Lahille,[1] in which, while giving a number of important original observations on the anatomy and bionomics of the Ascidians (and especially of the Compound forms) of the French coasts, the author introduces what I cannot help thinking in some respects an unfortunate attempt to remodel the classification of the Tunicata on lines which he communicated a few years ago to the French Association (Congrès de Toulouse, 1887), and now elaborates in detail. He regards the branchial sac as the most important organ in the Tunicata, and so it is in some respects; but that is not sufficient reason for regarding its modifications in structure as the sole characteristics of the primary groups. For example, the Appendicularians, instead of being called Larvacea or Copelata, and characterized by the presence of a tail containing the urochord, are placed in a group "Atremata," defined by the absence of stigmata in the branchial sac. The openings in question (stigmata) are not even such important structures as the primary branchial clefts (gill-slits), but are merely the secondary slits placing the cavity of the branchial sac in communication with the peribranchial or atrial cavity, and are of nothing like such high morphological value as the presence or absence of a urochord, and of the two primitive atriopores, and the other well-known characteristics employed in former classifications as distinguishing the Appendiculariidæ. Some of the Thaliacea are placed by Lahille in a group (Hemitremata) of primary importance, by themselves, because they have the stigmata rudimentary or imperfectly formed, while the other Thaliacea are united with all the remaining Tunicata, because they are supposed to be alike in having complete stigmata.[2]

Then, again, an altogether fictitious value is given by Lahille to the presence of internal longitudinal bars in the branchial sac, especially since he shows (as had been done by former writers) that these bars develop as outgrowths from the connecting ducts, and that intermediate conditions can be found in which the bars can neither be said to be absent nor present. He describes this condition in his new species *Perophora banyulensis*, and it is also present in *P. viridis*, Verrill, and in various other Simple Ascidians, as has been shown in the *Challenger* Reports and elsewhere.

---

[1] "Recherches sur les Tuniciers des Côtes de France" (Toulouse, 1890).

[2] Which, however, is not really the case. The apertures in the walls of the branchial sac in Lahille's "Eutremata" are not always homologous structures. In the genus *Culeolus*, for example, there are no true stigmata.

Such cases, although rather perplexing to the systematist, are perfectly natural from an evolutionist's point of view, and they certainly make one regard with some suspicion large groups founded upon any such one character. Consequently, Lahille's order "Stolidobranchiata," characterized solely by the presence of a particular kind of internal longitudinal bar in the branchial sac, is, in my opinion, a most unnatural assemblage of the families Polystyelidæ, Cynthiidæ, Molgulidæ, and Botryllidæ, which cannot be retained. It is not safe to trust to the modifications of structure of one organ in the detailed classification of a group, and it is especially unsafe where that organ is, as in the case of the branchial sac, of great physiological importance, and so is liable to be considerably modified in accordance with the mode of life in forms which are otherwise closely related. Morphological characters of less functional importance are more likely to be retained unaltered, and so indicate real genetic affinity.

Surely Lahille does not seriously mean to contend that the internal longitudinal bars in the branchial sac of the Botryllidæ, Cynthiidæ, &c., are different in any morphological sense from the similar bars found in other Ascidians, such as the Ascidiidæ. Although they may be slightly different[1] in their relations to the wall of the sac in these two groups, being attached throughout their length in *Botryllus* in place of only at the angles of the meshes as in *Ascidia*, and are therefore somewhat different in their development (ontogeny), there can scarcely be any doubt that in their origin (phylogeny) all such bars in the branchial sac are alike, and are therefore homologous structures.

(3) It follows from what has been said above in regard to the origin of the Compound Ascidians, that even though the group Polystyelidæ is placed (as was the case in the *Challenger* Report) in the Ascidiæ Compositæ, it is not thereby widely separated from its relations amongst the Simple Ascidians. If the sub-order Ascidiæ Compositæ is retained, then the Polystyelidæ must go in it, since they form definite permanent colonies with the ascidiozooids embedded in a common test; but of course these forms are very similar in many respects to *Styela* and *Polycarpa*—that being one of the points of contact between Compound and Simple Ascidians—and therefore I can agree fully with all that Lacaze-Duthiers and Delage say in favour of that relationship. The matter stands simply thus:—If Ascidiæ Compositæ is retained, the Polystyelidæ must be placed in it at the nearest point to *Polycarpa* amongst Ascidiæ Simplices; while if Ascidiæ Compositæ is abolished, the Polystyelidæ will form a family or a sub-family (it matters little which) alongside the Styelinæ under Ascidiæ Simplices. To go further, and break up even the genera of the Polystyelidæ, placing the species beside those Cynthiidæ they resemble most in the structure of the branchial sac, would be to give no value at all to the property of reproduction by gemmation and the formation of colonies.

(4) It has long been recognized that there are two groups of forms in the family Cynthiidæ, those which centre around *Styela* and those related to *Cynthia*, and when the remarkable stalked forms, such as *Boltenia* and the deep-sea genus *Culeolus*, had been added, I defined these three groups as sub-families under the names Styelinæ, Cynthinæ, and Bolteninæ. Leaving the last out of the question, we have the two former distinguished amongst other characters by the fact that the Styelinæ have never more than eight folds in the branchial sac, and have simple tentacles, while the Cynthinæ have always more than eight folds, and compound tentacles.

A few years ago these seemed well-established characters to which there were no exceptions. Last year, however, Lacaze-Duthiers and Delage published a preliminary account of a *Cynthia* from the French coasts, with only eight folds (as in Styelinæ) in its branchial sac; while Traustedt has discovered that the *Cynthia tesselata* of Forbes has four folds on the right side of the branchial sac and three on the left (like some Styelinæ), although the tentacles are compound (as in Cynthinæ); and I find that long ago Alder described the reverse case in *Cynthia tuberosa*, Macg., where there are twelve folds in the branchial sac (Cynthinæ), although the tentacles are simple (Styelinæ). Thus the two links required to unite the characters[1] of Styelinæ and Cynthinæ have been found, which is perfectly natural and satisfactory to the evolutionist, and the question for the systematist now is, Must these two sub-families be united? I think not. I believe that they are natural groups, and that they are really as widely separated from one another in their typical members as we ever supposed them to be, although not so completely isolated from one another by the extinction of intermediate forms.

If these interesting links, to which attention has just been drawn, and which are apparently not common nor widely distributed forms, had become extinct a few years ago, the Styelinæ and Cynthinæ would without question be justly regarded as widely separated groups. And the present position is merely that a few forms are known which if not bridging over at least lie as stepping-stones in the gap; while the vast majority of the species in question are clearly distinguishable by easily recognized characters into two definite sets. This last fact has an importance which entitles it to recognition. I am far from wishing to ignore the importance of such intermediate forms; in fact I am more likely, I fancy, to regard them with undue interest; but after all they are single species, minute twigs of the great branch under consideration, while long series of typical Styelinæ and Cynthinæ—the many species of *Styela* and of *Polycarpa*, of *Cynthia* and of *Microcosmus*—can be divided into two groups by their tentacles and their branchial folds, and I believe we are justified in giving expression to this natural grouping by retaining the two sub-families in our system of classification. It need not lead to any difficulties: the intermediate forms can be placed as an appendage to the sub-family taken first. We cannot now pretend to draw hard and fast lines round all our groups, a serial or a tabular classification will always give erroneous impressions, and in a phylogenetic arrangement the linking forms will appear in their proper places as little twigs between the two great branches.

(5) The genus *Botryllus* seems to contain an endless series of forms which might be (and many of which have been) described as separate species. Giard, twenty years ago, pointed out the great variability of the species in this genus, and described many varieties and local conditions, but the supply is not yet exhausted, and one is almost tempted to conclude that no satisfactory position can be taken up anywhere between the two extremes of either (1) regarding the whole genus (or even the family Botryllidæ) as an enormous protean species, or (2) describing nearly every colony as a separate species.

From the point of view of the systematist or speciographer who wants "good" and well-defined species, this group of Ascidians must be an abomination, but to the student of evolution it is full of interest. Here, if anywhere, characters can be seen varying in all directions and to almost all degrees, some variations becoming fixed while others remain indefinite. I am at present examining (with the help of my former student, Miss A. E. Warham, B.Sc.) the anatomical characters of a number of colonies of various *Botrylli* with the view of finding which characters, if any, can be relied on in distinguishing species or "forms," and I have just seen a series of ascidiozooids of *Botryllus smaragdus* in which the branchial tentacles, usually regarded as important features in the diagnosis of species, present all variations between eight and sixteen. Every one of the numbers 8, 9, 10, 11, 12, 13, 14, 15, and 16, is represented by one or more ascidiozooids, although 8 and 16 are those most commonly found. Also several definite arrangements, such as 2 large pigmented tentacles and 6 small, 3 large pigmented and 13 small, are present, and are connected by all possible gradations. Then, again, we find that the smaller set of these tentacles may be all alike, or may be of two sizes placed longer and shorter alternately, or they may be 2 shorter and 4 longer, or 2 shorter and 5 longer, or 3 shorter and 5 longer, or 4 shorter and 5 longer, or 6 shorter and 5 longer, and so on through the variations. Two or three of the extreme forms, if examined by themselves, might easily be regarded as distinct species.

---

[1] Even this difference is not constant. In some Botryllidæ, and I think in all Polystyelidæ and many Cynthiidæ, the relations of the bars in the adult are precisely as in *Ascidia*, *Ciona*, and *Ecteinascidia*.

[1] These are the chief characters, but there are others, such as the condition of the stomach and digestive glands.

I have heard it said, and I fancy it may be often thought, that since evolution has changed our conception of a species, the modern biologist need not concern himself with the description and nomenclature and delimitation of those assemblages of variable forms which are known as varieties and species. But to take such a course would be a great mistake. The theory of evolution has given taxonomy and speciography an additional and a very real interest. Now that we know just how much and how little the term species indicates, it has become of great importance that species and varieties should be re-studied from the evolutionary standpoint, that the relations of allied forms should be carefully investigated, the limits of their variation determined, and the effect of their environment ascertained. The Botryllidæ form a specially interesting group for such an investigation.

Many of these more general remarks will no doubt apply to other groups of organisms with as much force as to the Tunicata, but some of the instances discussed above may seem points of mere detail of no great general interest. I believe, however, that they are typical cases illustrating difficulties which may confront any specialist in the course of his endeavour to attain to that important object of biological investigation—a natural or genetic classification of animals and plants.

February. W. A. HERDMAN.

PHOTO-STELLAR SPECTRA.[1]

PROF. PICKERING, while retaining the four types of stellar spectra, finds that so many stars show an intermediate stage of development, that, in the Draper Catalogue, letters are substituted for the types. Thus, letters A to D denote stars of the first type; E to L, stars of the second type; M, stars of Type III.; while N is reserved for fourth type stars. It seemed of some interest to compare the photographic results with those obtained directly with the spectroscope. For the first and second types, the observations of Vogel ("Spect. Beob.," − 1° to + 20°) were used. The stars in the first four hours of R.A. which occur in both works were examined and tabulated, those being rejected where there was any uncertainty as to type in Vogel's observations. The following table shows the results thus obtained:—

VOGEL. Eye observation. Class.	PICKERING. Photographic observation. Letter.						
	A	B	E	F	H	I	K
I.	68	1	25	18	15	1	1
I. !	35	1	4	—	—	—	—
II.	4	—	5	—	28	—	1
II. !	—	—	—	—	—	—	—
II. !!	—	—	—	—	2	—	2

To show the differences in type, the following table has been drawn up:—

VOGEL. Stars. Number and Type.	PICKERING.	
	Type I.	Type II.
169 of I. ...	105 ...	64
42 of II. ...	4 ...	38

These tables show that, in the case of Type I., nearly half the stars observed with the eye are really Type II. according to the photographs; in the case of Type I.!, four out of the forty, although having a clearly pronounced first type spectrum to the eye, are really second type stars according to the photographs. In the case of the second type, four stars out of forty-two are really first type.

For the third type stars, Dunér ("Sur les Étoiles," &c.) was consulted, and the following results were obtained:—

DUNÉR. Eye observation. Type.	PICKERING. Photographic observation. Letter.						
	A	E	F	H	I	K	M
III.	—	—	—	19	2	—	8
III. !	—	—	—	24	2	1	22
III. !!	3	—	—	16	1	1	24
III. !!!	—	1	1	5	—	—	12

This table may be condensed as follows:—

DUNÉR. Type.	PICKERING. Type.			
	I.	II.	III.	Total.
III. to III. ! ...	— ...	48 ...	30 ...	78
III. !! to III. !!! ...	3 ...	23 ...	12 ...	38
Total ...	3	71	42	116

The photographs therefore show that only 36 per cent. are third type at all. In order to account for this very remarkable result, the words of Prof. Pickering may be quoted:—"The difference between this (the third) type and the second is much less marked in the photographic than in the visible portion of the spectrum. The most noticeable difference is that, in spectra of the third type, the intensity suddenly changes at the wave-length 476·2. Rays of greater wave-length than this are fainter than those that are shorter."

It will be seen that three stars of the third type appear as first type stars on the photograph. These are:—

(1) LL. 3717, 1h. 55m. $-\ 9^\circ\ 0'\cdot4$, Dunér III. !!: "Les bandes 2–9 sont fortement développées, très larges et sombres."

(2) D.M. $+\ 17^\circ\cdot1479$, 6h. 56m. $+\ 17^\circ\ 53'\cdot8$, Dunér III. !!: "Les bandes 2–8, et peut-être 9, sont visibles; elles sont très larges et fort obscures autant dans le vert-bleu que dans le rouge."

(3) τ^4 Serpentis, 15h. 31m. $+\ 15^\circ\ 25'\cdot9$, Dunér III. !!: "Les bandes sont larges et fortes, surtout dans le vert et dans le bleu."

Prof. Pickering states, in the preface, that when the brightness exceeds 6·5 it is difficult to classify the spectrum with certainty. The photographic magnitudes of these stars are 6·65, 6·45, 6·44 respectively.

As regards the fourth type, it is stated (p. 3) that "the letter N is reserved for spectra of the fourth type, although no star of this type is bright enough to appear in the Draper Catalogue, owing to the red colour of all such stars." This seems to be a mistake, as three fourth type stars are found in the Draper Catalogue. They are :—

---

[1] "Note on the Classification of Star Spectra in vol. xxvii. *Harvard Annals*, and on some Stars with Bright Lines."

Name.	R.A.	Decl.	Pickering's letter.	Photo. mag.	Dunér.
	h. m.	° ′			
D.M. + 17°1973	8 49	+17 36	H	6·65	IV. !!!
D.M. +68·617	10 38	+67 56	A ?	6·50	IV. !!!
D.M. + 76·734	19 25	+76 22	E	7·08	IV. !!!

These stars each occur on one plate only.

The photographs show that the following stars have bright lines in their spectra :—

Known variable stars : *ε* Aurigæ, *α* Orionis, *ζ* Geminorum, *α* Herculis, *β* Pegasi.

Suspected variable stars : *α* Cassiopeiæ, 66 Ceti, *ρ* Persei, *α* Tauri, *δ* Canis, *β* Geminorum, *α* Boötis, *β* Ursæ Minoris, *β* Cygni, *γ* Cephei.

Other stars showing bright lines, not hitherto detected, are : *τ* Ceti, *γ* Andromedæ, *κ* Persei, *α* Persei, *ν* Persei, 80 Tauri, *ζ* Aurigæ, *ζ* Cancri, σ^1 Ursæ Majoris, *o* Leonis,, *γ* Leonis, *ξ* Ursæ Majoris, 43 Comæ, *o* Boötis, *γ* Scorpii, *β* Coronæ, *ζ* Herculis, *η* Herculis, *μ* Herculis.

T. E. ESPIN.

SOME ASPECTS OF STAS'S WORK.

FOR the last thirty years Stas's work has set the standard of excellence in all that relates to atomic weight determination. The literature of the subject teems with references to his classic memoirs, which have come to be regarded by chemists in the light of canonical books. Admiration of the almost magical accuracy of Stas's results seems somewhat to have diverted attention from the rare philosophical insight displayed in the *plan* of his researches. Yet it is not too much to say that, while we owe the *conception* of the atomic theory to Dalton, Stas first placed the theory on a sound experimental basis.

It was in the year 1843 that Dumas and Stas's value for the atomic weight of carbon recalled attention to the hypothesis of Prout which had hitherto met with little favour on the Continent. The subsequent work of Dumas and of de Marignac led these chemists to support the hypothesis in a modified form. In 1860 appeared the first series of Stas's researches, " Sur les Rapport reciproques des Poids atomiques." In the introduction to his paper the author stated his conviction that these researches furnished proof, as complete as the nature of the subject admitted, that the hypothesis of Prout was a pure delusion —that there was, in fact, no common divisor between the atomic weights of the elements. In reviewing the work of Stas, de Marignac admitted the impossibility of reconciling the concordant results obtained by Stas and himself with even the modified form of Prout's hypothesis. Yet he regarded the dictum quoted above as too absolute in character. It was by no means established, he contended, that the constituents even of stable compounds are present *exactly* in the proportion of the atomic weights. De Marignac's criticism struck at the very basis of the atomic theory but this by no means deprived it of its weight. The laws of chemical combination are the experimental basis of the atomic theory, and Stas admitted that these laws had never been proved as " lois mathématiques." Writing in 1865, in the introduction to his " Nouvelles Recherches," he remarks that some of the fundamental ideas of chemistry, which are generally taken as having been proved, are as a matter of fact far from being so. He considers that the constancy of composition of chemical compounds has been experimentally established, but points out that this does not constitute a proof of the law of constant proportions, the law, viz., which states that the particular proportions in which two elements are combined in a certain compound is a *constant* proportion in all the compounds which contain those elements. This had never been proved, yet it was only in this way that the position of the atomic weights as constants of nature could be established. The so-called *law* of multiple proportions Stas referred to as an *hypothesis* of Dalton, pointing out that the very rough analyses on which Dalton relied—of which the error is frequently more than 10 per cent. —as well as the results obtained by Wollaston and by Gay-Lussac, were at most capable of establishing a "loi limité." The state of science at the time demanded a thorough re-examination of the basis of the atomic theory. Stas realized this need, and took upon himself the burden of the task. The conception and plan of the " Nouvelles Recherches sur les Lois des Proportions Chimiques " show the mind of a great thinker not less clearly than the results of the work exhibit the skill of a master in the art of experiment. The " Nouvelles Recherches " contains a verification as " loi mathématique " of the law of conservation of mass, in the complete synthesis of silver iodide, and the complete analysis of silver iodate. The constancy of composition of chemical compounds was subjected to a crucial test in the experiments on ammonium chloride, and the constant proportion between the combining weights of elements in different compounds was tested in the conversion of silver iodate, bromate, and chlorate, to the corresponding haloid salts. The law of equivalent proportions was verified by the concordant results obtained for the atomic weights of silver and of the alkali metals determined as functions of those of iodine, of bromine, and of chlorine respectively, oxygen forming the common standard. One cannot help regretting that the law of multiple proportions was not also made the subject of investigation. The most suitable examples occur among gaseous substances, and the operations of gas analysis were foreign to the methods of manipulation employed by Stas. The complete analysis of nitrous oxide was indeed contemplated in order to determine directly the atomic weight of nitrogen as a function of that of oxygen, but the idea was abandoned owing to the difficulty of constructing the necessary apparatus.

The work on the laws of combination furnished fresh materials for the examination of Prout's hypothesis. Stas's comments on the origin of this hypothesis possess a high degree of philosophic interest. The remarks to which we more particularly refer are the following :—" Lorsqu'on remonte à l'origine de l'hypothèse (de Prout) on s'aperçoit immédiatement qu'elle doit sa source à un préjugé ou, si l'on veut, à un opinion préconçue, concernant la simplicité des lois de la nature. Pendant longtemps les chimistes comme les physiciens, dès l'instant qu'ils ont vu certains faits se reproduire avec une *apparence* de régularité, ont cru à l'existence d'une loi naturelle susceptible d'être exprimée par une relation mathématique *simple*. . . . C'est à cette tendance, d'ailleurs très-naturelle, qu'on doit l'hypothèse de Prout." Dalton's enunciation of the law of multiple proportions is relegated by Stas to the same category as a generalization on insufficient data. Mendeleeff has remarked (Faraday Lecture, 1889) that the periodic law has shown that the masses of the atoms increase *per saltum*, in a manner which " is clearly connected in some way with Dalton's law of multiple proportions." Dalton was more fortunate than Prout. The combining proportions are expressible by a simple mathematical law, whilst the atomic weights are only to be represented by a complicated formula which may have some such form as that proposed by Carnelley.

The " Nouvelles Recherches " appeared in 1865. The first paper on the periodic system was read before the Russian Chemical Society in the spring of 1869. It is curious to reflect that the foundations of the atomic theory had hardly been made sure by Stas ere they were called upon to bear the magnificent structure raised by Mendeleeff.

V. C.

NOTES.

WE print elsewhere the proceedings of the important deputation to the Board of Trade on the subject of the Institute of Preventive Medicine. There can be no doubt that, after the statement made by the Minister, the registration of the Society will shortly be an accomplished fact; a few words in the deed of registration or a few minutes of reference between the Board of Trade and the Home Office are all that is needed to safeguard Sir Michael Hicks-Beach's official scruples. The importance of the deputation, however, will not be limited to this: it shows again, as in the case of the Art Gallery, that men of science are no longer willing to be snubbed by men in office.

THE annual meeting for the election of Fellows was held at the Royal Society's rooms, in Burlington House, on Thursday last, when the following gentlemen were elected into the Society:—William Anderson; Prof. Frederick Orpen Bower; Sir John Conroy, Bart.; Prof. Daniel John Cunningham; Dr. George Mercer Dawson; Edwin Bailey Elliott; Prof. Percy Faraday Frankland; Percy C. Gilchrist; Dr. William Dobinson Halliburton; Oliver Heaviside; John Edward Marr; Ludwig Mond; William Napier Shaw; Prof. Silvanus Phillips Thompson; Captain Thomas Henry Tizard, R.N.

MR. GEORGE HOLT, of Liverpool, last week sent the Treasurer of the University College there a cheque for ten thousand pounds as endowment for a Chair of Physiology, and candidates for the appointment are forthwith to be advertised for. It is only a few weeks since Mr. Brunner, M.P., sent a similar cheque to endow a Chair of Political Economy. The latter post has been offered to and accepted by Mr. E. C. K. Gonner.

THE Prince of Wales has fixed 4 o'clock on Wednesday, June 17, for the delivery by Lord Rayleigh of the first of the two lectures at the Royal Institution in connection with the centenary of the birth of Michael Faraday; and Friday evening, June 26, at 9 o'clock, has been appointed for the second of these lectures, which will be given by Prof. Dewar.

STUDENTS of geology were sorry to hear of the death of Dr. P. M. Duncan, F.R.S. He died on May 29 in his sixty-seventh year. Dr. Duncan was Professor of Geology at King's College, London, and was intimately connected with the Geological Society, of which he was President in 1876 and 1877. He was also a member of the Linnean Society.

MR. G. V. POORE, the Government Inspector, who has recently drawn up a report upon experiments performed on living animals during the year 1890, states that during the many visits he has paid to places licensed for the performance of such experiments, it has never fallen to his lot to see a single animal which appeared to be in bodily pain.

WE are glad to be able to announce that Mr. J. Graham-Kerr, of the University of Edinburgh, Naturalist to the Pilcomayo Expedition, has returned safely to this country, and has succeeded in bringing with him a portion of his natural history collections. As is well known, the *Bolivia*, in which Captain Page and his expedition ascended the Pilcomayo, was stranded in that river, in April 1890, in the middle of the Gran Chaco. After the death of Captain Page, which occurred while he was returning in a canoe down the Pilcomayo to get medical assistance, the *Bolivia* remained stuck fast nearly in one spot until March of this year, when Mr. Kerr, finding the vessel still immovable, and no prospects whatever of a rise in the river, decided to come away as best he could. After a very rough journey he reached Asuncion on mule-back, bringing as many of his light things as possible, and arrived in this country last week. Some very interesting letters of Mr. Kerr's, describing the natural history of the Gran Chaco, will be found in the two numbers of the *Ibis* for January and April last.

UNDER the will of Dr. Fothergill (1821), funds were bequeathed to the Society of Arts for the offer of medals for subjects, in the first instance, relating to the prevention of fire. A Society's Gold Medal, or £20, is now offered for the best invention having for its object the prevention or extinction of fires in theatres or other places of public amusement.

MESSRS. NEWTON AND CO. have been appointed philosophical instrument makers to the Royal Institution of Great Britain, an appointment which we believe has not been held by any firm for some years.

MR. JOHN T. BRUNNER, M.P., has been elected President of the Sunday Society in succession to Prof. G. J. Romanes. Mr. Brunner will deliver his presidential address at the Society's public annual meeting on June 27.

THE Société Botanique de France recently held its annual meeting in the little town of Collioure, near Perpignan, on the Mediterranean coast. After the meeting many excursions were made in the neighbourhood, which is interesting to botanists.

ON behalf of Prof. E. C. Stirling, of the University of Adelaide, South Australia, Prof. Newton communicated to the Zoological Society of London, at its meeting last week, a figure of the new Australian Marsupial, originally described by Dr. Stirling in this journal in 1888 (NATURE, vol. xxxviii. p. 588), together with some notes on this extraordinary animal. *Notoryctes typhlops*, as Dr. Stirling now proposes to call it, is a small mole-like animal belonging to the order of Marsupials, of which it forms an entirely new type. A general description of it has already been given, as above referred to, but Prof. Stirling now adds that the Marsupial bones are exceedingly small nodules, and escaped his notice at first. Four or five of the cervical vertebræ are fused, and there is a keeled sternum, an enormously thick and short first rib, which serves a purpose of buttressing the sternum in lieu of coracoids, and a bird-like pelvis. The penis is in the uro-genital canal, and the testes are external in front of it. The eyes are mere spots underneath the skin. The four specimens as yet received of *Notoryctes typhlops* were obtained in the centre of Australia, on the telegraph line between Adelaide and Port Darwin. The animal is said to burrow in the sand with great rapidity. A full description of it, it is understood, has appeared in the Transactions of the Royal Society of South Australia, but no copy of this journal has as yet reached England.

MM. GRÉHANT and Quinquaud conclude from some recent experiments on dogs that under the influence of alcohol muscular strength is much diminished.

PROF. JOHN M. COULTER, the well-known botanist, has been elected President of the State University of Indiana, located at Bloomington; and Dr. Douglas H. Campbell has been appointed Associate Professor of Botany at the new Stanford University of California.

ACCORDING to the *Botanical Gazette*, Mr. Thomas Meehan, of Philadelphia, is about to establish, in conjunction with his sons, a new journal of gardening and botanical miscellany. It will be called *Meehan's Monthly*, and the first number will appear on July 1.

WE learn from the *Journal of Botany* that Mr. Worthington G. Smith is preparing for the public gallery of the Botanical Department of the British Museum a series of 96 tables illustrating the British Fungi. Every species of the Hymenomycetes will be figured in its natural colours, the drawings being taken from Mr. Smith's own series already in the Museum, with others from original figures lent by Mr. Plowright and others.

THE number of *Neptunia* for April 30 gives a brief description of the following stations for the study of natural history:—

A marine zoological station has been founded at Endoume, near Marseilles, by Prof. Marion, especially for the study of the fishes of the Mediterranean. M. Alphonse Biosson is about to establish at his own expense a zoological station at Point-de-Grave, Gironde, with the especial object of promoting the investigation of the ornithology and entomology of the district. A marine station for physiology has been opened at Tamaris, near Toulon, under the direction of Dr. R. Dubois, Professor of Physiology in the Faculty of Sciences at Lyons.

The Berlin Academy of Sciences has recently made the following grants:—£100 to Dr. Fleischmann, of Erlangen, for researches in development; £30 towards the cost of publication of Dr. Krabbe's work, "Development-History and Morphology of the polymorphous Lichen Genus *Cladomia*"; £60 to Dr. Hartwig, of Bamberg Observatory, towards a series of observations on variation of the earth's axis; and £40 to Dr. Schmidt, of Halle, for researches on the light reflected from transparent bodies.

The following are subjects for prize competition, recently proposed by the Belgian Academy of Sciences:—Advancement of our knowledge of the relation of phenomena of solution to phenomena of combinations; discussion, on the basis of new experiments, of works relating to the kinetic theory of gases; perfection of the theory of approximative integration, both as regards rigour of methods and facility of application; researches on the embryonal development of a mammal belonging to an order the embryogeny of which has not yet been investigated; determination, by means of palæontology and stratigraphy, of the relations between formations referred by Dumont to his Laekenian and Tongrian marine systems; new researches on the formation of polar bodies of animals. The prizes are gold medals, of the value of 1000, 800, and 600 francs. Papers to be written in French, Flemish, or Latin, and sent to the Secretary before August 1, 1892.

Messrs. Richard Frères have issued an illustrated catalogue of measuring, controlling, and self-registering instruments for scientific and industrial purposes. A descriptive and illustrated list of instruments has also been published by the Cambridge Scientific Instrument Company.

The series of lectures annually given in the gardens of the Royal Botanic Society of London upon subjects connected with botany came to an end on Friday last, when Prof. Stewart, F.R.S., President of the Linnean Society, addressed a large number of visitors and students upon "The Relationship between Plants and Animals." The subject, he said, was one of much interest, as affording an explanation of the origin of many abnormal forms of vegetable growth. This is specially the case in tropical countries, where the struggle for existence is more intense than in colder climes; there the relationship is almost vital, some plants providing food, others shelter, to various kinds of ants, while these pugnacious insects, in turn, protect the plant from damage, by attacking any living thing which approaches it. One plant, known as the bull's-horn acacia, of Central America, provides a species of ant not only with food and drink, in the shape of tiny egg-like bodies upon the leaves—of which the ants are very fond—and a sweet fluid in special cavities on the stalk, but, in addition, furnishes a home in the hollow spines with which it is armed, these, when punctured by the ants, swelling out into perfect miniature bull's horns. In return the ants protect it from its enemies.

A series of experiments with regard to evaporation from free water surfaces and from earth saturated with water, in sun and in shade, has been recently made by Signor Battelli (*Il Nuovo Cimento*). He used three large tubs or vats, two holding water, and the third earth on a grating, to which water was admitted from a pipe entering the bottom. One water-tub and the earth-tub stood a few yards apart on the north side of a high wall; the other water-tub was in the open, and embedded in the ground. Signor Battelli's results are these:—The quantity of water evaporated from moist earth is in general greater than that from a free stagnant water surface, when the air temperature rises; but less, when the latter falls. With increasing wind-velocity, evaporation increases more rapidly from the water surface. The moister the air, the greater (other things equal) seems to be the ratio of the water evaporated from the moist earth to that from the stagnant water surface. The evaporation of a water surface exposed to the sun's rays is greater than that of a shaded one, not only by day, but in the following night. With rising temperature, the ratio between the water quantities from these two surfaces increases somewhat more quickly; with rising wind-velocity, this ratio diminishes.

The *Photographic Journal* of May 22 prints a paper by M. Léon Vidal, on photographic methods of obtaining polychromatic impressions. One of the writer's objects is to show that typographic and lithographic printers ought to find in photography "one of their principal auxiliaries." By its aid, he says, their work might be executed "more cheaply, more thoroughly, and more artistically."

On Sunday, June 7, there was a series of severe earthquake shocks in Italy. The centre of the seismic movement seems to have been in the province of Verona, but the disturbance was felt over a wide area. At Verona three strong shocks, preceded by a subterranean noise like the roaring of artillery, are reported to have occurred at 2 o'clock a.m. The inhabitants rushed in terror from their houses to seek safety in the open streets and squares. One of the assistant mistresses at a boarding-school died of fright. A number of chimneys were thrown down by the oscillation. Still more violent were the effects of the seismic disturbance at other places in the province of Verona, especially at Tregnago and Badia-Calavena. Shocks more or less severe were experienced at Brescia, Belluno, Ravenna, Parma, Modena, and Ferrara. The Central Meteorological Bureau reports that the earthquake was very strongly felt at Florence, where it awoke several people from their sleep. The disturbance also extended to Rome, as was shown by the seismograph, the time at which the shock was felt in Rome being 6 minutes and 40 seconds after 2 a.m. In Verona and the surrounding districts slight shocks continued to be felt on Monday and Tuesday. A large stream of lava issued on Monday from the new crater of Mount Vesuvius at the base of the central cone. Signor Palmieri, the Director of the Vesuvian Observatory, holds that this flow is directly connected with the earthquake shocks in the north, and points out that seismic disturbances in Italy generally stop when the eruption of Vesuvius begins.

In the Report of the Meteorological Service of the Dominion of Canada for the year ending December 31, 1887, just issued, it is stated that nearly eleven hundred warnings of approaching storms were issued by the Service during the year, and that of these warnings 972 were verified, being 88·9 per cent.

We have the pleasure of recording the issue of the first volume of the Publications of the Vatican Observatory, containing astronomical and meteorological observations for the last nine months of 1890. This Observatory was first established by Pope Gregory XIII. for astronomical purposes, and was used for regular meteorological observations from 1800–1821. After passing through several vicissitudes, a proposal was made, about the time of the Vatican Jubilee Exhibition in 1888, to reorganize the Observatory, and the present Pope accordingly re-established it on a sound basis, and it is now furnished with the best instruments procurable, both for direct observations and continuous registration in meteorology, astronomy, magnetism, and earthquake phenomena. It is proposed to carry on various researches, and to issue further volumes from time to time, as soon as sufficient materials are accumulated. The Director is Padre Denza, the founder of the Italian Meteorological Society, and Superintendent of the Observatory at Moncalieri.

CONSIDERING the question of determination of the evaporating power of a climate, Dr. Ule distinguishes (*Met. Zeits.*) between the intensity and the speed of evaporation. The latter can be well determined with an instrument like Wild's evaporimeter, and Dr. Ule sets forth, in a table, the monthly data of this for Chemnitz, compared with those of absolute humidity, "saturation deficit," and relative humidity. The agreement of the last with the evaporimeter figures is much better than that of the two others; still, there is considerable discrepance, and this is not explained (the author shows) by variations in wind-intensity. On the other hand, the data of the psychrometer show a remarkable parallelism with those of the evaporimeter, and by taking wind-variations into account the agreement is increased. Thus, from psychrometer-differences and wind variations, the evaporative power of a climate may be correctly estimated where an evaporimeter is wanting. Dr. Ule offers a new formula for estimating the layer of water evaporated in a given time, and tests it with two German climates, and one Australian.

IN an interesting paper on technical education in agriculture, reprinted from the Journal of the Royal Agricultural Society, Dr. W. Fream refers incidentally to the value of mathematical studies for the agriculturist. Dr. Fream's professorial experience at agricultural colleges has convinced him that a lad who is fairly competent in mathematical studies is "a good medium to work upon." "Those interested in the welfare of any young agriculturist should take care," he says, "that in his school days the study of mathematics is not ignored. The time devoted to acquiring proficiency in arithmetic, geometry, mensuration, and the elements of algebra and trigonometry—the latter really indispensable in the case of surveying—will never be regretted."

THOSE who are interested in questions relating to physical education will find much to please them in an excellent paper, in the June number of *Physique*, on natural history in public schools, by the Rev. T. A. Preston, late President of the Marlborough College Natural History Society. Many boys are not much attracted by games, and it seems hard that in such cases any sort of compulsion should be used. Why not have various alternative ways of securing exercise, any one of which might be chosen? Mr. Preston shows with great force, and in a very interesting manner, with how much advantage the study of natural history might in some instances be substituted for cricket and football. Boys out for a field excursion take a great deal more exercise, he maintains, than is ever taken at cricket. "With those who are keen naturalists," he says, "the mere exercise taken in any one day (not in an excursion) is often such that it might almost be said to require moderating. I have no hesitation in saying that, if exercise alone is to be considered, a field naturalist will take far more than any one at games."

MR. W. R. HILLIER, of the Indian Civil Service, has written a very curious monograph on the manners and customs of the Shan States. When a Shan becomes a father it is considered highly undesirable that he should drive pigs, carry the dead, bore holes, fill in holes in the ground, or indulge in mockery. "If either sex," writes Mr. Hillier, "die without marrying, the body, before burial, is banged against a stump, which is at the time considered as representing the husband or wife,"—a ceremony which is supposed to guard against the danger of unrequited affection in the next stage of existence. Marriage is simplicity itself. A young man takes a fancy to a young lady, and if the liking is reciprocated, she straightway accompanies him to his house as his wife. Next day the young man's parents meet the parents of the young lady, and after informing them of what has taken place, beg that "they may be forgiven for the intrusion," and ask that a day be fixed for the wedding. This request being granted—and apparently a refusal is not contemplated—the young lady returns to her parents. Divorce is easy also, the man merely giving his wife a letter permitting her to remarry, and the wife merely being required to pay an unwilling husband thirty rupees for release from an uncongenial mate. As to food the Shan is not an epicure, eating everything that is eatable; and indeed it is considered quite becoming, if he only be of high rank, to devour an enemy. This privilege, however, is accorded only to Bohs, or chiefs. The Shan theory of the cosmogony is that "the earth came out of the depths by means of white ants."

SOME further explorations have lately been made on the Upper Irrawaddy. Major Hobday, of the Indian Survey Department, with an escort of fifty Goorkhas, succeeded in getting as far north as latitude 26° 15′ up the Malika, or right branch of the river. Here the local tribes began to show opposition, and the party could not without fighting their way have proceeded further. The point reached was, however, only fifty miles south of that which Colonel Woodthorpe gained a few years ago in his explorations from the far north of Assam. This small gap will probably be crossed when the next attempt is made, as by that time the wild tribes will have learned from their neighbours that British officers have only friendly intentions towards them. Finding his progress barred to the north, Major Hobday turned due eastwards, with the intention of striking the Meka, which is supposed to be the main stream of the Irrawaddy. After exploring the course of this river for some distance, he will journey back through the hills along the Yunnan border, reaching Bhamo by land. He will thus be able to map a considerable extent of country.

AN interesting synthesis of troilite, the crystallized monosulphide of iron, FeS, which is so frequently found in meteorites and yet is never found in terrestrial rocks, is described by Dr. Richard Lorenz, of Göttingen, in the current number of the *Berichte*. A stream of dry sulphuretted hydrogen gas was led over a bundle of iron wire contained in a combustion-tube heated in a furnace. As soon as the wire became heated to dull redness, it became quite changed, becoming completely covered with innumerable brilliant little crystals. These crystals possessed a bright silver-white lustre when first obtained, but after a short time reflected a pale-green coloured light. On standing for some days, the crystals further changed in colour to blue and afterwards to brown, without the least change in the form being apparent. Under the microscope they appear to consist of well-formed six-sided tables of a bright steel-gray lustre. Prof. Groth, the eminent crystallographer, who has examined them, pronounces them to be hemimorphic hexagonal in form, isomorphous with wurtzite, the hexagonal variety of zinc sulphide. Any kind of iron may be substituted for the wire; whatever the variety employed, it always becomes covered with a crust of these crystals when heated in a stream of sulphuretted hydrogen, the only precaution necessary being to prevent the temperature from rising to the melting-point of monosulphide of iron. The crystals are readily detached from the iron, and upon analysis yield numbers very near the theoretical ones required by FeS. The largest and best developed individual crystals of troilite are obtained by diluting the sulphuretted hydrogen with an inert gas. Wurtzite, sulphide of zinc, ZnS, may also be readily artificially obtained in a similar manner by passing sulphuretted hydrogen over zinc heated to whiteness in a porcelain tube in a Schlösing furnace. When the tube, which is allowed to cool in the stream of gas, is broken, immediately beyond the portion which has been heated in the furnace a beautiful sublimate of crystals of wurtzite is found. They consist of well-developed hexagonal prisms, somewhat transparent and of a yellow colour, exhibiting, according to Prof. Groth, their hemimorphic nature in a most decided manner. In a similar way also Dr. Lorenz has artificially prepared greenockite, sulphide of cadmium, CdS. This synthesis is perhaps the easiest of all to effect, and it may readily be conducted in an ordinary combustion-tube. The metallic cadmium is placed in a porcelain boat, and commences to react with the sulphuretted hydrogen at a temperature just below its boiling-point. As soon as this temperature is attained, the porcelain boat and the portion of the tube beyond it become covered with magnificent long yellow skewer-like crystals of greenockite, which Prof. Groth finds to be of two kinds, hexagonal prisms isomorphous with troilite and wurtzite, and a new form of greenockite consisting of monoclinic crystals. Dr. Lorenz has further artificially prepared millerite, the sulphide of nickel, NiS, by the same method, obtaining in this case very minute but undoubtedly hexagonal crystals isomorphous with the three other sulphides above described.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus* ♀) from India, presented by Mr. Walter Fraser; a Rhesus Monkey (*Macacus rhesus* ♀) from India, presented by Colonel Beresford; a Great Black-headed Gull (*Larus ichthyaëtus*) from the Persian Gulf, four Macqueen's Bustards (*Houbara macqueeni* ♂ ♂ ♀ ♀) from Western Asia, three Chaplin Crows (*Corvus capellanus*) from Persia, presented by Mr. B. T. Ffinch, C.M.Z.S.; a Diamond Snake (*Morelia spilotes*) from New South Wales, presented by Mr. J. Hellberg; a Common Viper (*Vipera berus*) from Hampshire, presented by Mr. W. H. B. Pain; two Piapecs (*Ptilostomus senegalensis*) from West Africa, purchased; a Collared Fruit Bat (*Cynonycteris collaris*), four North African Jackals (*Canis anthus*), two Partridge Bronze-wing Pigeons (*Geophaps scripta*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE SPECTRA OF DOUBLE STARS.—A note on "The Discovery of Double Stars by means of their Spectra" is contributed by Prof. E. C. Pickering to *Astronomische Nachrichten*, No. 3034. When the components of a close binary system have similar spectra, relative orbital motion in the line of sight may cause a periodic doubling of the lines. But if the spectra be not similar any lines common to both ought to be conspicuously strong, and, provided the components have not equal and opposite velocities in the line of sight, ought also to be displaced with reference to other lines. Thus, if one component of a close binary system has a Group V. spectrum, like our sun, and the other a Group IV. spectrum, in which strongly marked hydrogen lines is the main feature, the resulting spectrum will have a composite character, and careful measurements should show that the position of the hydrogen line is periodically displaced when compared with the lines characteristic of the solar-type spectrum. α Canis Majoris is the brightest star having this composite spectrum, and the wave-length of the hydrogen line G, derived from a comparison with three lines of greater and three lines of smaller wave-length, was 434·09, which exceeds that derived from the solar spectrum by 0·03. Similar measures of the hydrogen line *h* gave a wave-length of 410·22, which also exceeds that in the solar spectrum by 0·03. From this displacement it would appear that if the phenomenon is due to the relative motion of a faint component, it is receding at the rate of 20 kilometres per second, as compared with the bright component. An examination shows that the following stars have the composite spectrum referred to: γ Andromedæ, H.P. 650, ε Boötis, α Scorpii, and β Cygni, all of which are known to be double; also π Persei, ζ Aurigæ, δ Sagittarii, 31 Cygni, and β Capricorni. In the cases of the last two, the spectra of the distant companions are distinctly separated from those of the chief stars. Although the strong hydrogen lines in the spectra investigated may be due to the presence of a faint companion, their intensity may also be due to many other causes. Thus, the strong hydrogen lines in the solar spectrum are not due to the integration of the spectrum of the sun and that of a companion. It is necessary, therefore, to determine whether the displacement is subject to a periodic variation or not, in order to test this method of discovering close binaries.

THE PERSEID RADIANT.—At the St. Petersburg Academy of Sciences, on April 22, M. Bredichin concluded, from the meteor observations made at Pulkova by ten astronomers in August 1890, "le courant des aérolithes n'est pas délimité par un point ou un petit rond, mais présente une surface considérable parsemée de radiants."

THE FLORA OF DIAMOND ISLAND.

DIAMOND ISLAND is situated at the mouth of the Bassein River, in the Indian Ocean, about five miles from Pagoda Point and eight miles from Cape Negrais, and in about 16° N. lat. It is of sandstone formation, somewhat exceeds a square mile in area, being about twice as long as broad, and the central part is a kind of plateau 60 feet or so above the level of the sea. With the exception of a small clearing for a telegraph station, the island is densely wooded down to the sea, but there is no mangrove belt on any part of the sandy coast, unless it be considered as represented by a few patches of *Avicennia officinalis*. Thus is the island described, though in greater detail, by Dr. D. Prain, Curator of the Herbarium of the Royal Botanic Garden, Calcutta, who has visited the island in H.M. Indian Marine Survey steamer *Investigator*, commanded by R. F. Hoskyn, R.N. Dr. Prain has published an elaborate analytical account of the flora in the Journal of the Asiatic Society of Bengal. He collected eighty-six species of flowering plants, three ferns, and four funguses, among which there was not a single novelty. The enumeration includes a number of cultivated plants, among them the coco-nut palm; but these are all of recent introduction. It is supposed that the island was not previously inhabited, and therefore that the vegetation of the dense wood overspreading the island is quite natural. The most interesting fact brought out is the evident affinity with the somewhat distant Andaman flora, pointing to a former connection. The Report is also valuable to the student of plant-distribution for the details it contains of the habitats and relative frequency of the component species of the vegetation.

W. BOTTING HEMSLEY.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Lord Walsingham, F.R.S., the High Steward elect, has issued a letter of thanks to the Senate, in which he promises to maintain the highest traditions of "our beloved University."

W. M. Hicks, F.R.S., late Fellow of St. John's College, and Principal of Firth College, Sheffield, has been approved for the degree of Doctor in Science. Dr. Hicks is the author of many important memoirs in mathematical physics, and of an approved text-book of dynamics.

Prof. Newton has been appointed a Manager of the Balfour Studentship Fund for five years.

A. H. L. Newstead, Scholar of Christ's, and E. W. MacBride, Scholar of St. John's, and President of the Union Society, have been nominated for research work at the Naples Zoological Station.

The Syndicate appointed for the purpose have selected a site for the Sedgwick Memorial Museum on the old Botanic Garden area, with a frontage to Downing Street. The proposed Museum will lie between the new Chemical Laboratory and the old Anatomical School, and complete one quadrangle of the new Museums group.

The following distinguished persons are proposed recipients of honorary degrees on June 16:—Lord Walsingham, F.R.S., the Marquis of Dufferin and Ava, K.P., G.C.B., Prof. Rudolf von Gneist, of Berlin, Sir Alfred Lyall, K.C.B., Sir Archibald Geikie, F.R.S., Antonin Dvořák, Prof. Karl Weierstrass, of Berlin, A. H. Taine, member of the French Academy, Dr.

Elias Metschnikoff, Director of the Paris Pasteur Institute, Prof. W. H. Flower, C.B., F.R.S., and Mr. W. E. H. Lecky.

Delegates from the seventh International Congress of Hygiene and Demography will be received by the Vice-Chancellor in the Senate House on Saturday, August 15.

The Museums Association hold their annual meeting in July in the buildings lately erected for the departments of Anatomy and Physiology.

Prof. Foster is appointed by the University a Member of Council of the Marine Biological Association.

The reference to the Syndicate on the question of Greek in the Previous Examination has been enlarged to include Latin also, and will be decided on by the Senate early in the October term. An animated discussion on the question took place in the Arts School, in which the claims of modern (non-classical) education for consideration by the University were strongly put forward by men of the highest classical distinction.

Mr. J. N. Keynes, the Secretary for the Local Examinations, has been approved for the degree of Doctor in Science.

An election to an Isaac Newton Studentship will take place in October. The value is £200 a year for three years from April 15, 1891. Candidates are to send their names and testimonials to the Vice-Chancellor between October 1 and 10.

It is proposed to affiliate the University to the University of Adelaide, South Australia.

The General Board of Studies propose that Dr. Ruhemann, hitherto Assistant to Prof. Dewar, shall be appointed a University Lecturer in Organic Chemistry.

A room in the new Physiological Laboratory is to be set aside for Psychophysics, and a grant of £50 for instruments is recommended by the General Board.

The Annual Report of the University Observatory contains a good record of work done and in progress. Prof. Adams is to be congratulated on the satisfactory way in which, notwithstanding his long and severe illness, the Observatory has been conducted.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 14.—"On the Theory of Electrodynamics." By J. Larmor, Fellow of St. John's College, Cambridge. Communicated by Prof. J. J. Thomson, F.R.S.

The electrical ideas of Clerk Maxwell, which were cultivated partly in relation to mechanical models of electrodynamic action, led him to the general principle that electrical currents always flow round complete circuits.

When this principle of circuital currents is postulated, the theory of electrodynamics is reduced to the Ampère-Neumann theory of complete circuits, of which the truth has been fully established. It leads, as shown by Maxwell, to the propagation of electrical action in dielectric media by waves of transverse electric displacement, which have the intimate relations to waves of light that are now well known.

The problem of determining how far these remarkable conclusions will still hold good when a more general view of the nature of dielectric polarization is assumed was considered by von Helmholtz in a series of memoirs.

The most general conception of the polarization of a medium which has been formed is the Poisson theory of magnetization. The magnetized element, whether actually produced by the orientation of polar molecules, or otherwise, may be mathematically considered to be formed by the displacement of a quantity of ideal magnetic matter from its negative to its positive pole, thereby producing defect at the one end, and excess at the other end. The element is defined magnetically by its moment, which is the product of the displaced quantity and the distance through which it is displaced. The displacement per unit volume, measured by this product, is equal to the magnetic moment per unit volume, whether the magnetized molecules fill up the whole of that volume or are a system of discrete particles with unoccupied space between them.

In the electric analogue we replace ideal magnetic matter by ideal electric matter; the displacement thus measured constitutes the electric displacement, and its rate of change per unit time represents the displacement current in the dielectric. We have to consider whether a displacement current of this type suffices to make all electric currents circuital; and it will be sufficient and convenient to examine the case of a condenser which is charged through a wire connecting its two plates. In the first place, this notion of electric displacement leads to the same distribution of potential between the plates as the ordinary one, adopted by Maxwell; for in the theory of induced magnetism there occurs a vector quantity of circuital character, the magnetic induction of Maxwell, of which the components are $-\mu(dV/dx)$, $-\mu(dV/dy)$, $-\mu(dV/dz)$, and which, therefore, leads to the characteristic equation of the potential

$$\frac{d}{dx}\left(\mu\frac{dV}{dx}\right)+\frac{d}{dy}\left(\mu\frac{dV}{dy}\right)+\frac{d}{dz}\left(\mu\frac{dV}{dz}\right)=0,$$

corresponding to the one given above. If the displacement in the dielectric is $-\kappa(dV/dx)$, $-\kappa(dV/dy)$, $-\kappa(dV/dz)$, then

$$\mu = 1 + 4\pi\kappa.$$

The displacement in a unit cube may, of course, be considered as a displacement across the opposite faces of the cube.

Now, considering the case of a plane condenser, let F be the electric force in the dielectric between the plates; then the displacement is κF. Let σ be the surface density of the charge conducted to a plate; then the effective electrification along that plate will be of surface density $\sigma' = \sigma - \kappa F$; therefore, by Coulomb's principle,

$$\begin{aligned} F &= 4\pi\sigma' \\ &= 4\pi(\sigma - \kappa F); \end{aligned}$$

so that

$$\sigma = \frac{\mu}{4\pi}F = \kappa F + \frac{1}{4\pi}F.$$

Thus the current is not circuital, but there is an excess of the surface density conducted to the surface over the displacement current from the surface, which is equal to $F/4\pi$.

The specific inductive capacity, as determined by static experiments on capacity, is here measured by μ, the coefficient in the expression for σ.

In addition to this discontinuity at the face of a condenser plate, the induction in the mass of the dielectric will not be circuital unless the electric force is itself circuital, which it is not in the general form of the electrodynamic theory.

The most general type of electrodynamic relations which is consistent with the established theory of complete circuits, is discussed on the basis of von Helmholtz's work, but with avoidance of certain restricting conditions introduced by him, the chief conclusion being as follows:

In a complete circuit the one thing essential to the established theory is that the electric force integrated round the circuit should be equal to the time rate of change of the magnetic induction through it, and, therefore, have an ascertainable value, though its distribution round the circuit is a subject of hypothesis. The conclusion that waves of transverse displacement will be propagated in a dielectric with velocity $K1^{-\frac{1}{2}}$ will hold good if we assume any form whatever for the electric force which does not violate this one relation, and also assume an electrostatic polarization of the medium, equal at each point to the electric force multiplied by a constant $K_1/4\pi$.

The increased generality which can be imparted to the theory merely leads to various modes of propagation of a condensational wave.

If K_2 denote the specific inductive capacity of the medium, measured in static units, this polarization constant K_1 is equal to $K_2 - 1$; and the velocity of the transverse waves is the ratio of the electric units of quantity in a medium of unit inductive capacity multiplied by the static value of $K_1^{-\frac{1}{2}}$. The correspondence of the refractive index for the simpler media with $K_2^{-\frac{1}{2}}$, as well as direct measures of the relative velocities of electric waves in other media, give for the value of this velocity the same ratio multiplied by $K_2^{-\frac{1}{2}}$. These values can be reconciled only by the limiting form of the theory of polarization which is equivalent to Maxwell's theory.

May 28.—"On the Anatomy and Physiology of *Protopterus annectens*." By W. N. Parker, Ph.D., F.Z.S., Professor of Biology in University College, Cardiff. Communicated by W. H. Flower, F.R.S.

The work which has resulted in the present paper was begun in Freiburg in the summer of 1888, when the author was fortunate enough, owing to the generosity of Prof. Wiedersheim, to obtain a number of fresh specimens for examination. As so many interesting points presented themselves at an early stage in the research, a short preliminary notice, without illustrations, was published in the following autumn (*Berichte d. Naturforsch. Gesellschaft zu Freiburg i. Br.*, vol. iv. 1888; see also NATURE, vol. xxxix. p. 19) This notice merely forms the basis of the present paper, in which the whole subject has been worked out in greater detail. A number of new facts are recorded, some of the author's earlier conclusions modified, and the paper illustrated with 11 plates containing 71 figures.

With the exception of certain special details, the structure of the skeleton and of the nervous and muscular systems are not described, the paper consisting mainly of an account of other organs which have not received so much attention from previous observers, and of a comparison of *Protopterus* with the other genera of Dipnoi, so far as their structure is known, as well as with other Ichthyopsida.

A number of details with regard to the habits of *Protopterus* in captivity are given.

The paired extremities show no connection with the cheiropterygium, and, in spite of their considerable nerve-supply, are evidently greatly degenerated structures as regards their free portions. Sensory organs are not present on them, and they therefore cannot have a tactile function. Their distal ends, like the apex of the tail, are very variable, and can undoubtedly be reproduced when lost by accident. The tail is almost certainly not primarily diphycercal, and shows signs of a possible origin from a heterocercal form.

The epidermis on the whole most nearly resembles that of Perennibranchiate Amphibians, and gives rise to simple multicellular glands, as well as to very numerous closely-packed goblet-cells, which produce the gluey secretion as well as the main substance of the capsule which surrounds the animal during the torpid state.

The integumentary sense-organs are similar to those of fishes and larval Amphibians. The relations of the sensory organs of the trunk are similar to those seen in young stages of Fishes and in Amphibian larvæ, while in the case of the head they resemble those which are typical for adult Fishes. End-buds, similar in structure to the taste-buds of Fishes and Amphibians, are present on the tongue and oral epithelium.

As regards its general structure, the olfactory organ most nearly resembles that of Elasmobranchs, but the presence of posterior nostrils raises it to a higher level. The position of the anterior nostrils beneath the upper lip is probably to be accounted for as an adaptation in connection with the torpid state. Four straight and two oblique muscles are present. The sclerotic is fibrous in young animals, and islands of cartilage first appear at the points of insertion of eye-muscles, and then gradually extend so as to chondrify the whole. The eye resembles that of Amphibians; a *processus falciformis* and *campanula Halleri* are absent, and no ciliary muscles were observed, though possibly present; almost all the pigment of the eye is ectodermic.

No specialized glands are present in connection with the greatly folded epithelium of the oral cavity. The lips contain no muscles. The tongue, as well as the palate, is covered with blunt conical papillæ, on which the taste-buds are situated. A horny cap is developed over each tooth from the overlying epithelium, which apparently becomes cut through by the sharp edges and points of the teeth, and which probably corresponds to the *cuticula dentis*. The thyroid and thymus are described.

A ventral, as well as a fenestrated dorsal, mesentery is present supporting the intestine. The author compares the so-called urinary bladder ("cloacal cæcum") with the "processus digitiformis" of Elasmobranchs. A spleen and pancreas are present, embedded in the thin walls of the stomach, and extending on to the proximal part of the intestine; they are covered externally by sparse muscular fibres as well as by the peritoneum. The relations of the pancreas therefore most nearly resemble those met with in Ganoids and certain Teleosteans. The pancreas is deeply pigmented, and its ducts open into the bile-duct. The pigmented walls of the intestine and the spiral valve are very thick, owing to the abundance of lymphoid tissue contained within them. With the exception of the bursa entiana, the internal walls of which are raised up into a number of deeply pigmented oblique folds, the whole of the mucous membrane of the stomach and intestine is perfectly smooth, and there is no indication of any differentiated gastric or intestinal glands.

Cilia are present on the epithelium throughout the stomach and intestine. A layer of small-celled lymphoid tissue directly underlies the epithelium. In the spleen and lymphoid organs of the intestine two kinds of tissue are present. Large migratory cells are present in both kinds of tissue, many of which inclose yellowish granules. Gradations between these and rounded cells of a deeper yellow or brown colour can apparently be made out, and cells appearing to be intermediate forms between these and the ordinary black, branched pigment cells can also be seen. It seems probable that the yellow granules mentioned above are due to the disintegration of red corpuscles, which are ingested by leucocytes, and then undergo some change, whereby the latter gradually pass into the condition of black pigment cells, which migrate through the epithelium, and are so got rid of. The muscular layers are very thin.

The question as to the mode of digestion and absorption of the food in *Protopterus* is discussed.

The branchial apparatus shows signs of considerable reduction. The pulmonary apparatus, on the whole, more nearly resembles the air-bladder and its duct of certain Ganoids than the lungs and laryngo-tracheal chamber of Amphibians. The pulmonary branches of the vague cross one another at the base of the lungs.

The blood is remarkable for the large size of its elements, which is only exceeded in the case of *Proteus* and *Siren*, as well as for the large proportion of white corpuscles in comparison with the red ones. Two forms of the former are described. The chief points of interest with regard to the blood-vessels are: (1) the paired pulmonary artery, the left supplying the ventral, and the right the dorsal, aspect of the lungs; (2) the single post-caval and persistent left posterior cardinal vein; and (3) the single caudal vein, giving rise to a right and a left renal portal.

No external sexual differences could be observed, and amongst the specimens examined, females were the more abundant. The urino-genital organs are surrounded by masses of tissue resembling the large-celled lymphoid tissue of the gut, but differing from the latter in becoming largely converted into adipose tissue. The kidneys probably represent the mesonephros, and their duct the Wolffian duct; nephrostomes are absent.

In unripe males, delicate Müllerian ducts are present. The sperm is conducted to the exterior by a duct, which is probably formed in connection with the testis, quite independently of the excretory apparatus. The seminal tubules are directly connected with it, and it opens into the base of the Müllerian duct, the rest of which apparently aborts completely. Unlike most of the tissue elements, which are very large, and closely resemble those of the Amphibia, the spermatozoa are very minute, and are remarkable in possessing *two* vibratile flagella attached to the carrot-shaped "head." The generative organs of the female bear a striking resemblance to those of Amphibians. The oviduct corresponds to the Müllerian duct; the epithelium covering its internal folds shows signs of degeneration similar to those which have recently been described amongst Urodeles.

An account of the mode of life of *Protopterus* during the torpid period is given. The cocoon is provided with a "lid," perforated by a hollow funnel-shaped tube, which passes between the lips of the animal, and thus forms a passage for the respiratory current. The source of nutriment during the summer sleep lies in the adipose tissue in connection with the gonads and kidneys and alongside the notochord in the tail, as well as in the lateral muscles, some of which, especially in the caudal region, undergo a granular degeneration. Very probably the latter is the precursor of the fatty degeneration, and, in all probability, leucocytes are the active transporting agents of the degenerated material. This assumption would help to explain the large development of lymphoid tissue in the body of the animal.

The systematic position of the Dipnoi is briefly discussed in the light of the new facts brought forward in the present paper. Although the Dipnoi present many points of resemblance to Fishes on the one hand, and to the lower Amphibians on the other, their connection with any living forms of either class is probably a very distant one, and it is inadvisable to classify them amongst the Fishes. Owing to the absence of ontological evidence, and to the incompleteness of our knowledge of the palæontological history of the Dipnoi, it is impossible to construct a genealogical tree which will show, with any approach to accuracy, the probable connection between them and other Ichthyopsidan types. The most that can be said at present, with anything like certainty, is that the Dipnoi are the isolated survivors of an exceedingly ancient group, which was probably related to the ancestors of existing Fishes and Amphibians. Amongst the former, the connection seems to be closest to the

Elasmobranchs, more particularly to the Chimæroids on the one hand, and to such an ancient Selachian type as *Chlamydoselache* on the other; but, at the same time, the Ganoids probably arose from the common ancestral stock not very far off. Though retaining many primitive characters, the Dipnoi, and more especially *Protopterus* and *Lepidosiren*, are in some respects highly specialized, the specialization being largely due to a change of habit.

"Method of Indexing Finger Marks." By Francis Galton, F.R.S.

Sufficient proof was adduced by me in a memoir read November 27, 1890, before the Royal Society (Phil. Trans., B, 1891), of the extraordinary persistence of the papillary ridges on the inner surface of the hands throughout life. It was shown that the impression in ink upon paper of each finger tip, contained on the average from twenty-five to thirty distinct points of reference, every one of which, with the rarest exception, appeared to be absolutely persistent. Consequently that it was possible to affirm with practical certainty whether or no any two submitted impressions were made by the fingers of the same person.

In the present memoir I shall explain the way in which finger prints may be indexed and referred to after the fashion of a dictionary, and on the same general principle as that devised by A. Bertillon with respect to anthropometric measures, whose ingenious method is now in regular use on a very large scale in the criminal administration of France and elsewhere. I desire to show how vastly the practical efficiency of any such method as that of A. Bertillon admits of being increased by taking finger prints into account in the way to be described.

It must not, however, be supposed that the use of indexing finger marks is limited to the above purpose, the power of doing so being equally needed for racial and hereditary inquiries. I do not dwell upon these applications now, simply because I am engaged in making them, and the results are not yet ready to be published. I ought, however, to mention that a great increase of experience has fully confirmed my earlier views, that finger marks are singularly appropriate subjects of anthropometric study owing to many distinct reasons. The impressions are easily to be made by anyone who has the proper appliances at hand. They are as durable as any other printed matter, and they occupy very little space. The patterns are usually sharp and clear, and their *minutiæ* are independent of age and growth. They are necessarily trustworthy, and no reluctance is shown in permitting them to be taken, which can be founded either upon personal vanity or upon an unwillingness to communicate undesirable family peculiarities.

Without caring to dwell on many of my earlier failures to index the finger prints in a satisfactory way, my description shall be confined to that which has proved to be a success. It is based on a small variety of conspicuous differences of pattern in each of many digits, and not upon the numerous minute peculiarities of a single digit. My conclusions are principally based on a study of the impressions of all 10 digits of 289 different persons, but the tables given in the memoir refer only to the first 100 on my list. These are sufficiently numerous to serve as a fair sample of what we might always expect to find, while they are not too cumbrous to print and to discuss in full detail.

Though I have spoken and shall speak only of impressions, it is not really necessary in forming an index to make any impression at all. All the entries that appear in it may be derived directly from the fingers themselves.

I rely, for the purpose of indexing, on the three elementary divisions of primaries, whorls, and loops. They are severally expressed by the numerals 1 and 2, 3 and 4, 5 and 6. The reason of this double numeration is that most of the patterns have a definite axis. Those that are formed by ridges which proceed from only one side of the finger, lie in a sloping direction across its axis, the slope being directed according to the side from which the supply of ridges proceeds. All normal slopes, or those that are (roughly) parallel to a line drawn from the tip of the forefinger to the base of the little finger, as well as all the patterns that have no definite axis, are expressed by the odd numerals, 1, 3, or 5. All abnormal slopes are expressed by the even numerals 2, 4, or 6. It cannot be too strongly insisted that the words right and left are ambiguous, and must not be used here.

The forefingers are the most variable of all the digits in respect to their patterns, their slopes being almost as frequently abnormal as not; the third fingers rank next; the little finger ranks last, as its pattern is a loop in nine cases out of ten. I therefore found it convenient not to index the fingers in their natural order, but so that the sequence of the numerals which express the patterns on the digits should be divided into two groups of three numerals, and two groups of two numerals, as 355, 455, 55, 35. The first group 355 referring to the first, second, and third fingers of the left hand; the second group 455 to the first, second, and third fingers of the right hand; the third group 55 to the thumb and fourth finger of the left hand; the fourth group 35 to the thumb and fourth finger of the right hand. The index is arranged in the numerical sequence of these sets of numbers.

Before translating the patterns into numerals, I find it an excellent plan to draw symbolic pictures of the several patterns in the order in which they appear in the impression, or in the fingers themselves, as the case may be, confining myself to a limited number of symbols [a list of those which have thus far sufficed is given in the memoir; 5 of them are symmetrical symbols, and 9 are tailed and duplicated for the reasons given above, one of each pair being inclined to the right, and the other to the left. The total number of these hieroglyphs is consequently 23]. A little violence has of course to be used now and then, in fitting some unusual pattern to one of these symbols. But we are familiar with such processes in ordinary spelling, where the same letter does duty for different sounds, as *a* in the words *as*, *ask*, *ale*, and *all*. The merits of this process are many. It facilitates a leisurely revision of first determinations; it affords an adequate record of the character of each pattern; it prevents mistakes between normal and abnormal slopes; it prevents confusion when changing the sequence of the entries from the order of the impressions to that used in the index; and, lastly, it affords considerable help to a yet further subdivision of the patterns.

In making a large and complete index, the symbols would, of course, be cast as movable types, and be printed with the letterpress.

It appears from the 100 cases that are printed in the memoir that there were 83 different varieties of index numbers when all 10 digits are used. Consequently the average number of references required to pick out a single well-defined case from among these 100 would be equal to 100 divided by 83—that is, to about 1¼. I do not expect from my own reiterated experiences that there would be much trouble due to transitional cases, after a standard collection of doubtful forms had been collected and numbered, so as to insure that different persons should follow a common standard. I find much uniformity in my own judgment.

Owing to the large effect of correlation, an index based on all the 10 digits is not much superior in efficiency to one that is based on six—namely, upon the first three fingers of both hands. In the 100 different sets there are, as already said, 83 varieties of pattern in the one case, and there are 65 in the other, which roughly accords with the relative efficiency of 5 to 4. It is, therefore, a fair question whether it is worth while to impress all the 10 digits. The chief advantage of doing so is to add to the volume of evidence, and to supply data which mutilation, or bad scars, or obliteration due to some exceptional cause might render of value. The three fingers of both hands are more than twice as useful for an index as those of one hand only; again, the three fingers of one hand are nearly twice as useful as two only. I may mention that for my present inquiries into racial and hereditary patterns I am, for various reasons, dealing only with the first three fingers of the right hand, and slightly rolling the forefinger, so as to obtain a full impression of its pattern on the side of the thumb.

When searching through a large number of prints that bear the same index number, in order to find a duplicate of a particular specimen, it is a very expeditious method to fix on some one well-marked characteristic of a minute kind, such as an island, or inclosure, or a couple of adjacent bifurcations, that may present itself in any one of the fingers, and in making the search to use a lens or lenses of low power, fixed at the end of an arm, and to confine the attention solely to looking for that one characteristic. The cards on which the finger marks have been made, may then be passed successively under the lens with great rapidity.

[It is proposed to exhibit specimens illustrative of this and of the previous memoir, together with appliances for taking impressions from the fingers, at the approaching *soirée* of the Royal Society.]

Physical Society, May 22.—Prof. W. E. Ayrton, F.R.S., President, in the chair.—Mr. C. J. Woodward exhibited Dr. Schobben's form of lantern stereoscope. This instrument consists of a double lantern, by which the two pictures of a stereoscopic slide are projected on a screen. The two pictures are coloured complementary tints by placing pieces of red and green glass in front of the lenses, and each observer views the overlapping images through spectacles, the eye-glasses of which are also coloured red and green. The stereoscopic effect is very striking. Mr. Boys stated that he had tried to obtain a similar result with the aid of polarized light, by viewing two polarized images through Nicol prisms. No effect was obtained, owing to elliptic polarization produced by the screen, but he thought that if a dead-gold screen had been used instead of an ordinary one, the effect might have been observed.—Prof. Perry, F.R.S., showed a new form of steam-engine indicator. A galvanometer mirror is fixed excentrically to a steel disk, forming one side of a chamber communicating with the cylinder. The pressure of the steam bulges out the disk, and causes the mirror to deflect a ray of light thrown on it in the ordinary way. A rotation of the mirror at right angles to the former is imparted by the movement of the piston-rod. The ray of light traces out the diagram on a screen suitably placed, and the complete figure is continuously visible, owing to the persistence of impressions. This indicator possesses advantages over other forms, in being free from errors due to friction or oscillations of the springs, and the alteration of their elasticity due to temperature changes. The errors of ordinary indicators are considerable at high speeds, owing to the ripples introduced into the indicator diagram. If the natural period of the springs is one-twentieth of the time of a revolution, the diagram is fairly free from ripples, but if it is as much as one-tenth, no amount of friction in the indicator will prevent ripples forming. In the new indicator, the natural period of the disk can be made very short. The steel disks are easily removable, and can be proportioned to suit different pressures and speeds. For experimental and teaching purposes it is advantageous to see at once the alterations in the diagram caused by changes of load, pressure, &c. Several diagrams were exhibited to the meeting. In reply to Prof. Carus Wilson, Prof. Perry stated that the deflection was proportional to the pressure in the cylinder within the limits any particular disk was intended for. Mr. Addenbrooke thought the instrument an important improvement on its predecessors, and considered it would prove of great service to electrical engineers. Mr. Swinburne said a peculiar merit of the indicator was that it could be permanently attached to an engine like an ordinary pressure-gauge. He suggested the use of a small telescope instead of the ray method. The President thought that the instrument could be modified so as to be useful for analyzing the shape of the curves representing alternating currents.—On Blakesley's method of measuring power in transformers, by Prof. Perry, F.R.S. This paper refers to the supposed error in Mr. Blakesley's formula due to the fact that transformers show magnetic leakage. The proofs of the formula hitherto given have been obtained by treating the equations in the manner first adopted by Dr. Hopkinson. On this system the reactions of the primary and secondary currents are represented by the equations—

$$V = R_1C_1 + P\frac{dN}{dt}, \quad 0 = R_2C_2 + S\frac{dN}{dt},$$

where P and N are respectively the turns on the primary and secondary coils, and N is the magnetic flux between the coils. Here it is assumed that there is no magnetic leakage, and the author thinks that on this account the method is inferior to the original method of Maxwell, in which the induced electromotive forces are expressed in terms of coefficients of self and mutual induction. On the assumption that there are no eddy currents, Maxwell's equations are—

$$V = R_1C_1 + L_1\dot{C}_1 + M\dot{C}_2; \quad 0 = R_2C_2 + MC_1 + L_2\dot{C}_2,$$

in which although L_1, M, and L_2 may not be constant, it may be assumed that they are respectively proportional to P^2, PS, and S^2, if there is no magnetic leakage; and if the amount of magnetic leakage bears a constant proportion to the whole flux, the three quantities may still be assumed proportional to each other, although M^2 is less than L_1L_2. From these equations we obtain

$$VC = R_1C_1^2 - R_2\frac{M}{L_2}C_1C_2 + \frac{L_1L_2 - M^2}{L_2}C_1\dot{C}_1.$$

Hopkinson puts down the last term as zero, but owing to the very rapid rate at which C_1 changes, the last term is very important, even though M may be but a small percentage less than $\sqrt{L_1L_2}$. On integrating this equation, the first two terms on the right-hand side yield Blakesley's formula, and the last term vanishes in the integral, because, however great the magnetic leakage may be,

$$\int C_1\dot{C}_1 dt = 0,$$

when taken over a period because the functions are periodic. Mr. Blakesley's formula thus appears to hold, whatever the magnetic leakage. The paper contains several tables of calculations showing the effect of magnetic leakage on the value of the terms in the equation. Mr. Blakesley said he doubted the correctness of the assumption that the value of M was the same in the two equations, and thought that the result arrived at must be incorrect. Dr. Sumpner did not doubt that if the coefficients could be considered constant, the formula was true whatever the leakage, but he did not consider that the action of transformers justified such an assumption. If the formula were true, it would also hold if there were eddy currents, as these would merely produce the effect of additional secondary coils. He had analyzed Blakesley's method by using a modification of the Hopkinson equations, and had shown that the power as estimated by Blakesley's formula had to be lessened by the fraction represented by the expression

$$X = \frac{\int x\dot{A}_p \int A_s dtdt}{e + \int A_pA_s dt},$$

where A_p and A_s are the instantaneous values of the primary and secondary currents, and x is such that $N_p = N_s(1 + x)$ where N_p and N_s are the fluxes of magnetism through the primary and secondary coils at the same instant; e is a negligibly small quantity compared with the rest of the denominator. In obtaining this factor no assumptions whatever had been made, and it was easy to see that if A_p and A_s could be assumed sine functions, and x a constant, the value of the factor X became x simply. In only one case did X reduce to zero, and that was when x was a sine function of the same period as A_p and A_s. He believed that in actual transformers x was approximately constant. Mr. Swinburne pointed out that the split dynamometer was merely a watt-meter, and stated that he had transformers which, owing to magnetic leakage, would indicate an efficiency of over 100 per cent. if tested by Blakesley's method. If this method gives an efficiency of 96 per cent., and leakage causes a drop of 2 per cent. in E.M.F., the real efficiency is only about 94 per cent. He thought that the assumption that the currents followed a sine law was equivalent to supposing that there was no loss in hysteresis. The President said that no one would be more glad than himself to find that Mr. Blakesley's method was accurate, but he could not agree with Prof. Perry that Dr. Hopkinson was wrong in abandoning the academical method of Maxwell. Prof. Perry replied to the various points raised in the discussion.—A paper on current and potential difference analogies in the methods of measuring power, by Prof. W. E. Ayrton and Dr. Sumpner, was postponed.

Royal Microscopical Society, May 20.—Dr. R. Braithwaite, President, in the chair.—The President said he regretted to have to announce the deaths of two of their Honorary Fellows, Dr. Carl von Naegeli, of Munich, and Prof. J. Leidy, of Philadelphia.—Mr. C. L. Curties exhibited a new form of Mayall's mechanical stage, recently manufactured by Zeiss, which gave upwards of an inch motion each way, and merely required to be clamped on the pillar of the microscope when wanted for use.—Mr. Watson exhibited and described a microscope which he had recently made specially to meet the wants of Dr. Van Heurck, of Antwerp. Mr. Mayall, after criticizing the design, for which, he understood, Dr. Van Heurck was responsible, concluded by expressing his regret that Dr. Van Heurck's specification should have resulted in the production of the microscope exhibited. Mr. E. M. Nelson and the Rev. Dr. Dallinger also criticized the instrument adversely.—Mr. Grenfell exhibited the photograph of a small organism, the nature of which he had been as yet unable to determine; some zoologists and botanists to whom he had shown it were unable to say whether it was vegetable or animal in its nature. He also wished to mention that in the Botanical Gardens, Regent's Park, there were considerable numbers of a free-swimming infusorian known as *Tintullus*. It was remarkable for its chitinous lorica.

Claparède mentioned its having been found at Berlin; but hitherto it had only seemed to have been found in sea-water.—Prof. Bell said they had received a communication from Mr. J. B. Rosseter describing the development of *Tænia lanceolata* from the duck, the cysticercoid form of which had not been previously known. He (Mr. Rosseter) had fed the ducks with some of the *Cypris* known to be infested with the parasite, and after some weeks opened the ducks and found the tapeworm mentioned. It was interesting to get the life-history of another tapeworm worked out.—Mr. E. M. Nelson read a note on the subject of lateral development in photography, and a paper on the use of monochromatic light in microscopy, and exhibited the model of a new and simple apparatus for obtaining the same by means of a glass prism. Mr. Nelson also described a new projection microscope fitted with a special condenser made of three flint lenses so as to embrace the whole cone of 82°. The novelty about it was the system of collecting the light, by which a beam of 4¼ inches was brought down to 1¼ inches, and by passing through two lenses placed in the water-trough, a beam of parallel rays of great intensity was obtained for use in projecting the image upon the screen. Afterwards Mr. Nelson gave an exhibition on the screen.

Geological Society, May 27.—Dr. A. Geikie, F.R.S., President, in the chair.—The following communications were read:—On the lower jaws of *Procoptodon*, by R. Lydekker. After reviewing Sir R. Owen's writings upon the large extinct Kangaroos for which he established the genus *Procoptodon* in 1874, the author describes two mandibular rami from the clay beds of Miall Creek in the neighbourhood of Bingera, N.S.W., which belong to this genus, and from their characters and a comparison of them with the lower jaws in the British Museum, he maintains that this part of the skull indicates two very distinct species of the genus, for which he retains the names *P. rapha*, Ow., and *P. goliah*, Ow., though it is possible that the types of those two species are really specifically identical, in which case the name *P pusio*, Ow., might have to be adopted for one of the species described.—On some recently exposed sections in the Glacial deposits at Hendon, by Henry Hicks, F.R.S. In this paper the author brings forward evidence obtained from sections exposed in gravel-pits and deep cuttings made for the purpose of laying down the main sewers, to show that Glacial deposits had been spread out to a much wider extent over the Hendon plateau than had hitherto been supposed, and that they had reached down the slopes to below the Ordnance-datum line of 200 feet. He further mentions that there is evidence to show that these deposits have extended in a south and south-west direction across the Brent and Silk Valleys, and now occur on most of the heights in the parishes of Kingsbury and Willesden. As the sands, gravels, and Boulder-clay which cover the Hendon plateau and the neighbouring heights are found to rest on an undulating floor of London Clay, and to follow the contours of the hills and valleys, the author considers that it is clear that the main physical features of this portion of North-west Middlesex were moulded at a very early stage in the Glacial period, and before the so-called Middle sands and gravels and overlying Upper Boulder-clay with Northern erratics were deposited. He believes that at this time there could have been no barrier of any importance to prevent these deposits from extending into the Thames Valley, and that the evidence clearly points to the conclusion that the implement-bearing deposits on the higher horizons in the Thames Valley should be classed as of contemporaneous age with the undoubted Glacial deposits at Hendon, Finchley, and on the slopes of the Brent Valley, which they so closely resemble. The author is therefore satisfied that man lived in the neighbourhood of the Thames Valley in the early part of the Glacial period; probably, he thinks, in pre-Glacial times. This paper led to a discussion, in which Mr. H. B. Woodward, Mr. J. A. Brown, Dr. Hinde, Mr. Monckton, and the author took part.

Entomological Society, June 3.—Mr. Frederick Du Cane-Godman, F.R.S., President, in the chair.—Mr. E. B. Poulton, F.R.S., exhibited living larvæ of *Endromis versicolora*, and commented on their habits.—Mr. W. F. H. Blandford called attention to the fact that the larvæ of *Liparis monacha* remained in small groups on the bark of the tree for about a week after emerging from the eggs, and that this fact was taken advantage of by the German foresters to destroy them. Also that he had himself verified the statement that uric acid can be detected in the Malpighian tubes of insects. Mr. McLachlan, F.R.S., agreed that the demonstration that the Malpighian tubes were of the nature of renal organs was now satisfactory.—Mr. C. J. Gahan exhibited two species of Coleoptera that he considered to possess a mimetic resemblance.—Mr. Tutt exhibited a hybrid between *Amphidasis prodromaria* and *A. betularia*, obtained by Dr. Chapman. Mr. Stainton, F.R.S., commented on the fact that the two insects appeared at different times; and Mr. Tutt stated that the *A. betularia* had been subjected to forcing, so as to cause it to emerge at the same time as *A. prodromaria*.—Mr. Tutt also exhibited forms of *Caradrina*, some of which he said were considered distinct on the Continent, though they were not recognized as such in this country, viz. *Caradrina taraxaci* (*blanda*), *C. superstes*, Tr., from Sligo, and *C. superstes*, H. S., considered as synonymous with *superstes*, Tr., but apparently more closely allied to *C. ambigua*.—Mr. Bristowe exhibited varieties of *Arctia menthastri*, some of which had been fed on mulberry and others on walnut; no difference was observed in the variation.—Mr. G. Elisha exhibited larvæ in their cases of *Coleophora vibicigerella* and *C. maritimella*.—Mr. A. G. Butler communicated a paper entitled "Additional Notes on the Synonymy of the Genera of Noctuid Moths."

Zoological Society, June 2.—Prof. W. H. Flower, C.B., F.R.S., President, in the chair.—The Secretary read a report on the additions that had been made to the Society's Menagerie during the month of May 1891, calling special attention to a female Water-buck Antelope (*Cobus ellipsiprymnus*) from British East Africa, presented by Mr. George S. Mackenzie, and to three Blanford's Rats (*Mus blanfordi*) from Kadapa, Madras, received in exchange, new to the collection.—Mr. Sclater made some remarks on the animals which he had noticed during a recent visit to the Zoological Gardens of Paris, Ghent, Antwerp, Rotterdam, Amsterdam, and the Hague.—Prof. Newton, F.R.S., exhibited (on behalf of Prof. Stirling, of the University of Adelaide), a drawing, being the first received in Europe, representing the remarkable new Australian Mammal lately described by Prof. Stirling as *Notoryctes typhlops*, which was stated to be the Mole-type of the order Marsupialia.—The Secretary exhibited (on behalf of Mr. F. E. Blaauw) specimens of the Long-tailed Tit, shot in Holland, and sent to this country for the purpose of ascertaining whether they belonged to the British form (*Acredula rosea*) or the white-headed Continental form (*A. caudata*).—Mr. F. Finn exhibited a hybrid Duck bred in the Society's Gardens, believed to be bred between a male Chilian Pintail (*Dafila spinicauda*) and a female Summer-Duck (*Æx sponsa*).—A communication was read from Dr. O. F. von Moellendorff containing a revised list of the Land and Freshwater Shells of Perak, with descriptions of some new species.—A communication was read from Dr. G. E. Dobson, F.R.S., containing a sketch of the derivation and distribution of the Mammals of the order Insectivora found in the New World.—Mr. G. A. Boulenger read a report on Reptiles, Batrachians, and Fishes of which specimens had been collected for the West Indian Exploration Committee in some of the Lesser Antilles, and deposited in the British Museum.—A communication was read from Mr. Hamilton H. Druce containing an account of the Butterflies of the family Lycænidæ obtained by Mr. C. M. Woodford in the Solomon Islands.

CAMBRIDGE.

Philosophical Society, May 18.—Prof. Liveing, Vice-President, in the chair.—The following communications were made:—On parasitic Mollusca, by Mr. A. H. Cooke.—Mr. W. Bateson exhibited and explained models of double supernumerary appendages in insects; and also a mechanical method of demonstrating the system upon which the symmetry of such appendages is usually arranged.—On the nature of the excretory processes in marine Polyzoa, by Mr. S. F. Harmer. This communication was the result of an occupation of a University table at the Zoological Station at Naples during the Easter Vacation of 1891. Observations were made on the manner in which various artificial pigments were excreted in *Bugula* and in *Flustra*, on the lines adopted by Kowalevsky (*Biolog. Centralblatt*, ix., 1889–1890, pp. 33, &c.) for other invertebrates. The general result of the experiments was to show that excretion is not performed by organs comparable with nephridia, but that this process is carried on by free mesoderm cells, and to some extent by the connective tissue and by the walls of the alimentary canal. Evidence was obtained to show that the periodic loss of the alimentary canals leading to the formation of the "brown bodies" may be regarded as, to some extent, an excretory process.

PARIS.

Academy of Sciences, June 1.—M. Duchartre in the chair.—Calorimetric researches on humic acid derived from sugar, by MM. Berthelot and André. The experiments show that humic acid is a polybasic acid which may be caused to unite with three equivalents of potash to form insoluble salts: one salt described is monobasic, stable, and formed with the evolution of 18 calories, an amount comparable with that evolved when alkaline salts are formed by the action of strong acids. Many other properties of this acid are given.—Analysis of the light diffused by the sky, by M. A. Crova. The observations recorded extend from December 1889 to the same month in 1890. From the results it appears that the blue colour of the sky is most intense in the months of December, January, March, and September; and shows minima in July, August, and November. Roughly, the blue colour is deepest in the winter, and palest in summer; spring and autumn give sensibly the same results. A comparison of the intensities at different hours of the day indicates that a maximum blue coloration occurs in the morning and a minimum at the hottest hour in the day.—On Abelian equations, by M. A. Pellet.—On a new method of determining the vertical motion of aërostats, by M. André Duboin. The methods usually employed by balloonists to determine their state of vertical motion are by means of a barometer, or by throwing out light bits of paper and observing whether they ascend or descend relatively to the balloon. The author has devised an apparatus having the same object, on the principal of Kretz's differential manometer, and claims for it a sensibility 150 times greater than the ordinary mercurial barometer.—New models of copper oxide batteries, by M. F. de Lalande. A 35 per cent. solution of potash is the liquid employed. In it dips a conglomerate of copper oxide and sand covered with a thin porous layer of metallic copper, and one or two zinc plates. A cell thus constituted is shown to be practically constant for three or four days, and is said to work for years without getting out of order.—Determination of molecular weights at the critical point, by M. Philippe A. Guye. Using Van der Waals's formula, the author deduces $d = 1146\frac{\delta\theta}{\pi(1670 + \theta)}$, where d is the critical density with respect to air, δ the critical density with respect to water—that is, the weight of the substance in grams occupying a volume of one cubic centimetre at the critical state—θ the absolute temperature, and π the pressure in atmospheres. It is then shown that the values of d obtained by means of this empirical formula are equal to the molecular weights of the substances investigated divided by 28·87.—Research on the separation of metals from platinum, and in particular of palladium and rhodium in the presence of common metals, by MM. A. Joly and E. Leidié. The platinum or palladium are converted into soluble nitrites by the addition of potassium nitrite, and are thus separated from other metals.—On the specific heats of some solutions, by M. W. Timofeiew. Alcoholic solutions of bichloride of mercury and cadmium iodide were used. It is shown that the difference between the molecular specific heat of the solution and solvent is sensibly equal in the case of both salts, the mean value being 52. Taking this value to represent the molecular specific heat of the salt in solution and the specific heats of the alcohols employed to be expressed by the formulæ,

$$C^{\text{methyl}} = 0{\cdot}56755 + 0{\cdot}001633t\text{ ; }C^{\text{ethyl}} = 0{\cdot}53574 + 0{\cdot}002132t\text{ ;}$$

it is shown that the observed and calculated specific heats of the solutions are very nearly the same in each case.—On the oxidation products of uric acid, by M. C. Matignon. The heats of formation and combustion of the principal derivatives of uric acid are considered.—On the employment of ammonium selenite for the identification of alkaloids, by M. A. J. Ferreira da Silva. The use of ammonium sulphoselenite for the detection of morphine and codeine was suggested by M. Lafon in 1885. The author shows how the method can be extended to other alkaloids.—On the development of the liver of Nudibranchiates, by M. H. Fischer. The research shows that the liver of Nudibranchiates is formed to a great extent by the left hepatic lobe of the embryo, and that the hepatic organs in two very different groups of Mollusca, the Lamellibranchiates and Nudibranchiates, are homologous productions.—The *Isaria*, a parasite of the larva of the cockchafer, by M. Alfred Giard.—The genera of the group of Clusia, and in particular the genus *Tovomita*, by M. J. Vesque.—On some supporting elements of the leaves of Dicotyledons, by M. E. Pée-Laby.—Diffusion of three distinct forms of titanium oxide in the Cretaceous strata of Northern France, by M. L. Cayeux. A microscopic examination of the residue after treating chalk with an acid leads the author to believe he has recognized the three crystalline forms of titanium oxide—rutile, anatase, and brookite.—The lichens on mulberry-trees, and their influence on silk culture, by M. G. Hallauer.—On the employment of carbon bisulphide against aërial parasites, by M. H. Quantin.

AMSTERDAM.

Royal Academy of Sciences, May 30.—Prof. Van de Sande Bakhuyzen in the chair.—Dr. Bakhuis Roozeboom treated of the solubility of mixed crystals of isomorphous substances. Admitting the absolute homogeneity of such crystals, according to the recent researches of Retgers, it is possible to deduce, by thermodynamical reasoning, that, when p and T are taken as constants, equilibrium is obtained when to a proportion a of the components in the mixed crystals, correspond two definite values C_1 and C_2 for the concentrations of the components in the aqueous solution. From the analogy between the said equilibrium and that between a liquid and a gaseous phase, composed of two substances, are further deduced some general conclusions as to the behaviour of solutions of two isomorphous salts when they are evaporated. This is done both for the case in which the mixed crystals form a continuate series, and that in which they present a hiatus. The latter was found in studying the solubility of $KClO_3$ and $TlClO_3$. Solid mixtures were obtained at 10° and 1 atm. from 0–36·3 and from 97·9–100 per cent. $KClO_3$. In the evaporation of any one solution, it tends to a composition, which is necessary to deposit the two kinds of crystals between which the hiatus exists.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Bacteria and their Products: Dr. Sims Woodhead (Scott).—Einleitung in die Theoretische Physik; Zweite umg. und verm. auflage; V. von Lang (Braunschweig, Viewig).—A Manual of Forestry, vol. ii.: Dr. W. Schlich (Bradbury).—The British Noctuæ and their Varieties, vol. i.: J. W. Tutt (Sonnenschein).—Practical Work in Organic Chemistry: P. W. Streatfeild (Spon).—Katalog der Bibliothek der Deutschen Seewarte zu Hamburg (Hamburg).—Catalogue of the Fossil Birds in the British Museum (Natural History): R. EGYPTIAN IRRIGATION.

THE "Note" on the above subject by Sir Colin Moncrieff, which we publish this week, will prove pleasant reading to all who have the welfare of Egypt at heart. To those who have known that country intimately in the past, the brief record of progress in irrigation since the British occupation will recall the horrors of the *corvée*, and the torturing of the wretched peasantry by tyrannical farmers of the taxes; and to engineers the record will imply, not only that all those atrocities have been abolished, but further that some of the most difficult and important engineering problems of recent times have been successfully solved by Sir Colin Moncrieff and the able staff under his control. Nothing is exaggerated, but we have in the "Note" a plain and modest statement of the quiet and unostentatious execution of works the mere discussion of the difficulties of which had occupied the time of the predecessors of Sir Colin for the previous quarter of a century without anything useful resulting.

It will be only necessary to refer to one or two matters to establish this proposition. In paragraph 10, Sir Colin announces that the Barrage has been completed, and placed in a condition to fulfil its original purpose, for the sum of about £460,000. Contrast this with the published statement of M. Linant, a former engineer-in-chief of the Egyptian Government, who, in 1872, expressed a doubt whether it would not cost more to repair the existing Barrage than to build an entirely new one, and further says: "If, at the time when the Barrage was commenced, steam-engines had been what they are to-day, one would certainly have advised Mehemet Ali to abandon his project of a Barrage for the establishment of pumping-machinery." Even at that time, M. Linant thought it was not too late to consider whether it would not be better to abandon the idea of repairing the Barrage; and to assist in the determination of the question he submitted an estimate of the cost of pumping, amounting to £465,000 per annum, which, he thought, the cultivators could well afford to pay.

We have already stated that Sir Colin Moncrieff has effected the same result by a single expenditure of £460,000 instead of by an annually recurring one of £465,000. By means of the completed Barrage the whole summer supply of the Nile is thrown on to the lands, so obviously there is no work for pumps, and the vast cost of the same is saved to the country. Although national feeling runs high in France, we cannot but think that French engineers will rejoice that the world-renowned Barrage of the Nile, the design of which by M. Mongel was approved of by the Council of the Ponts et Chaussées in 1842, and carried into execution during the ensuing ten years, has at last, after thirty years' practical inutility and failure, been finally completed by their worthy compeers and successors in Egypt—the British engineers—whose experience, gained in the great irrigation works of our Indian Empire, has been as zealously utilized in securing the success of a great French work as it would have been in carrying out a new one of their own design.

One other matter in Sir Colin Moncrieff's "Note" may be referred to—namely, the drainage recently effected No doubt, the fact enforced upon Indian engineers by numberless experiences—that high-level perennial irrigation must be accompanied by drainage works if soil and people are to remain in a healthy condition—was not well known to the French projectors of summer irrigation works in Egypt; and, as a consequence, whereas magnificent canals carrying 5000 cubic feet and upwards per second were constructed, no corresponding means were provided for draining the superfluous and often saline water off the lands. Sir Colin tells us that the mileage of the drains at present is not less than 1500. When we consider that, in addition to these vast works of improved irrigation and drainage, a steady reclamation of marsh-land has been going on, we have reason as a nation to be proud of the good work which our countrymen have carried on in Egypt; as, whatever may happen in the future, the fact of the British occupation will, from its successful applications of science, be indelibly stamped upon the face of the country for all time, and its memory will for other reasons live honourably in the traditions of the emancipated and much-enduring fellaheen.

PHYSIOLOGICAL PSYCHOLOGY.

Leitfaden der physiologischen Psychologie. In 14 Vorlesungen. Von Dr. Th. Ziehen, Docent in Jena. (Jena: Gustav Fischer, 1891.)

THIS little volume will be welcome to a good many students of psychology, both in Germany and beyond. Anyone who has had to look up the newer researches in experimental psychology in Germany knows the serious difficulty of gaining easy access to them. They are scattered over a whole heterogeneous mass of serial and other publications. Now we have to look into an avowedly psychological journal or brochure, but more frequently still into physiological works, and not infrequently into journals for psychiatry. The explanation is obvious. Psychology, in passing into the objective and experimental phase, is broadening its base to an almost perplexing extent, and is encroaching more especially on the domain of physiology. Hence the need of a volume like the present work, which aims at giving the beginner a conspectus of the psychological field. We want such a book badly in English, the only available one, that of Prof. Ladd, being at once incomplete on certain sides, and in part too metaphysical. Meantime we can recommend Dr. Ziehen's "Vorlesungen" as exceedingly well adapted to give the student a clear idea of the scope and the methods of the new science of physiological psychology.

Dr. Ziehen marks off physiological from what he calls transcendental psychology by the differentia that it deals with psychical processes as attached to cerebral functions. Psychophysic, the branch of investigation opened up by Weber and Fechner, he includes under physiological psychology as that part which aims at exact measurement. This seems to be a satisfactory way of mapping out the ground. The standpoint of the physiological psychologist is indicated in the assumption that every psychical process must be thought of as having a concomitant physiological process. This, too, though it would exclude such a "physiological psychology" as that of Ladd, seems a reasonable way of viewing the matter. Further, the author proceeds to set forth the typical form of psycho-physical process as reflex, and he considers that every known development of the psychical phase must be capable of being viewed as an incident in such a reflex process. Here Dr. Ziehen meets the real difficulty in psychology, and, as we see, meets it boldly. From the physiological point of view we are bound to take the reflex as our starting-point, and to view the most intricate plexus of cerebral processes as merely an expansion of the intermediate central stage of this reflex. But can the same mode of treatment be applied to the intricate interweavings which constitute our mental life? As mere events in time, synchronizing with neural events, they appear to be susceptible of being thus regarded, and this, as the author rightly contends, is precisely the way in which the physiological psychologist has to conceive of psychical phenomena.

Starting, then, with the reflex, of which the writer gives an admirable account by way of introduction, he proceeds to deal with the psychical process in its three successive stages, viz. sensation, answering to the afferent or sensory section of the nervous process; ideation, or, as he puts it, association, answering to the expanded form of the central section; and action, answering to the efferent or motor section. The account of sensation is fairly full, and up to date. Perhaps the treatment of the relation of stimulus to sensation (Weber's law) is proportionately too long. The discussion of the interpretation of the facts is original and interesting. The author does not, like most recent physiologists, view the logarithmic ratio of stimulus to sensation as a purely physiological relation, due to what Mr. James has recently called the friction of the nerve-machine, but connects it with a more general psycho-physical law formulated by Hering, viz. "that the purity, distinctness, or clearness of a sensation or idea depends on the relation in which the weight of the same, *i.e.* the magnitude of the corresponding psycho-physical process, stands to the collective weight of all simultaneously present sensations and ideas, *i.e.* to the sum of the magnitudes of all the corresponding psycho-physical processes." At the same time the author is far from clear when he speaks of the conscious comparison of intensities as an "associative activity." This is an example of a tendency among the younger physiological psychologists to force psychical processes into a physiological framework. Comparison cannot, as Münsterberg's ingenious but futile attempts plainly show, be regarded as *merely* an associative process, though of course it depends on association, and in this way can be correlated with a nervous process. It must, however, be said in justice to Dr. Ziehen, that he is commendably free from the common tendency of physiologists to ignore psychical distinctions. Thus it is quite refreshing to find a physiologist contending that black and grey are positive sensations, having each its distinctive quality, like white or blue. It may be added that special interest is given to the exposition of sensation, as of the other psychical phenomena, by the frequent bringing in of the biological point of view, and the suggestion how, by the process of natural selection, particular psycho-physical arrangements have been brought about and rendered permanent.

The account of sensation is supplemented by a chapter on the affective or emotional tone of sensations, *i.e.* their pleasurable or painful aspect. Here, again, we have frequent references to the Darwinian theory, as when it is suggested, *à propos* of the fact that extreme intensities of skin-sensation, pressure, heat and cold, lose their distinctive sensational quality, and become purely affective phenomena or pains, that this arrangement has come about owing to the circumstance that in the evolution of the zoological series "intensive mechanical and caloric stimuli constitute the earliest, the most frequent, the most direct, and the greatest danger to the animal organism" (p. 85). The author refers the whole of the difference in affective tone among colours, and among combinations of musical sound, to association. This seems to be going too far. The contrast between the exhilarating effect of the warm colours, and the quiet effect of those at the violet end of the spectrum, seems to be connected in part with the difference in the underlying nervous processes; and this is certainly true, as Helmholtz has shown, with respect to the emotional aspect of certain accords, *e.g.* the major and minor triads.

Coming now to the account of the idea (image and concept), we note that Dr. Ziehen differs from the majority of contemporary psychologists in assigning a separate cortical element to the sensation and to the idea. These different cells (the author, in spite of Lewes's attacks on the cell-superstition, talks of the individual cell as the seat of a sensation) are closely connected, and in this way the after-effect of sensations in memory, as also the reflex effects of ideas in exciting sensations, as in hallucinations, are accounted for. The writer elaborates his peculiar anatomical hypothesis in an ingenious way. He seems to admit, however, that it is a pure hypothesis, for the facts of "mental blindness" referred to are not apparently put forward as a proof; and it may be added that rightly viewed they do not seem even to suggest the hypothesis. One may add that it appears to lack the only possible justification of such a hypothesis, viz. that it simplifies the interpretation of the facts. The other supposition, that the sensation and the idea involve the same group of central elements (not the same single cell), is more reasonable in itself, and seems to offer a readier explanation of most of the phenomena.

The account of the psycho-physical process in association is less clear and instructive than most of the exposition. The author follows Münsterberg a good way at least—in reducing all association to one form, viz. contiguous, and more particularly simultaneous, association. But the diagrammatic representation of the processes strikes one as needlessly complicated by the hypothesis of separate ideational nerve-cells. Much better is the account at the close of this lecture of the way in which the different psycho-physical factors co-operate and modify one another in the actual concrete processes of reproduction. Dr. Ziehen is particularly happy in explaining the great variability of the sequences of our ideas from moment to moment. The account of the ideational stage is completed by a discussion of the relation of association to judgment and reasoning—which is a little hasty, and ignores some of the main difficulties of the subject, of attention and the voluntary control of the thought-process, and of the abnormal modifications of ideation in mental disease, sleep, and hypnosis.

The unfolding of the third and final stage, voluntary action, with which the volume concludes, offers little that is noteworthy. The author adopts the new and growingly fashionable view that all our active consciousness, sense of muscular effort, and so forth, is the result of afferent nerve processes, and he proceeds, much in the manner of Münsterberg, to resolve all volitional processes into complexes of sensations and ideas, more particularly ideas of movement. This seems to lead logically to the denial of any distinctive active or volitional psychosis answering to ideational or emotional psychosis; and Dr. Ziehen is not afraid to express this denial, and fortifies his position by the debatable statement that psychiatry, while acknowledging a special variety of intellectual and of emotional disturbance, knows no such thing as a distinct volitionary disturbance. It is to be added that the exposition concludes with a particularly good discussion of the final results of psycho-physical research. The author here shows himself a genuine psychologist, and while insisting upon the invariable concomitance of a physiological factor in psychical phenomena, is so far from regarding the psychical as a non-essential and negligible accompaniment of the material process, that he closes in a quite Kantian strain by reminding us that the psychical chain is that which is known primarily and immediately, and which as such must always possess more reality for us. J. S.

ACHIEVEMENTS IN ENGINEERING.

Achievements in Engineering. By L. F. Vernon-Harcourt, M.Inst.C.E. (London: Seeley and Co., Limited, 1891.)

THE object of this book is to describe some of the principal engineering works carried out during the last fifty years at home and abroad. The author has avoided technical phraseology to a great extent, thus making a very interesting subject as clear as may be to the general reader. Much subject-matter has been gleaned from many sources, and these are amply enumerated in the preface.

The London Metropolitan Railways and the New York elevated railways are described in chapter i. The growth of the Metropolitan system is very interesting, and is traced from the opening of the first section from Paddington to Farringdon Street in 1863 to the completion of the "Inner Circle" from the Mansion House to Aldgate in 1884. The author states that when the Metropolitan Railway was first designed, it was intended that the traffic should be worked by smokeless, hot-water locomotives not burning fuel, as it was supposed that the trains would be small, and that "foreign" locomotives would not travel over the line to any important extent. This, however, was not carried out, and locomotives of the ordinary type were adopted. The ventilation therefore proved defective, and even to this day improvement is greatly needed in many sections. The bad atmosphere is, of course, due to the locomotives in use, and the emission of steam considerably adds to the nuisance. Locomotive engineering is surely able to cope with this trouble. The dead weight of the trains might be considerably reduced with advantage, and the engines designed with ample condensing arrangements, even if the latter had to be attached to the engine as a separate vehicle. The boilers should, of course, be large enough to steam well with the ordinary blower, so that all the exhaust might be condensed.

The Metropolitan Railway represents an engineering achievement novel in many respects and made under circumstances of peculiar difficulty. On the other hand, the New York elevated railways illustrate how the American engineers solved a similar problem in a very different manner. Owing to the cost of "burrowing underground," as the author aptly describes it, they rejected the underground scheme, and for the same reason a railway on an arched viaduct was also considered undesirable. The railways have been carried along the streets, raised above the street traffic on girders resting upon wrought iron lattice columns standing at convenient places on the line of the curb of the pavements. An illustration is given representing a street in New York and the elevated railways running on each side. No payment has been made for placing these columns along the streets, and no compensation has been paid for damages to residential property fronting the railways. The author estimates the depreciation in value, due to the presence of the railway, as not less than 50 per cent. The cost per mile will therefore be considerably less than in the case of the London Metropolitan Railway, in which case all these items were heavily paid for. The London railway cost about £575,000 per mile, whereas the New York elevated railways only cost about £81,000 per mile.

Chapter ii. describes railways across the Alps, the Rocky Mountains, and the Andes. On p. 30 we find an interesting diagram representing the gradients and altitudes of the heavy portions of these lines, from which it is evident that the lines in North and South America are at higher elevations and are more subject to snow than the highest of the Alpine railways, and more severe gradients are to be found. Take, for instance, the heavy gradient on the Mexican Railway, rising 6400 feet in 54 miles, the maximum gradient being 1 in 25. This portion of the line is worked by Fairlie engines, which the author attempts to describe on p. 56.

The author in describing the Festiniog Railway says that the traffic is worked up the long incline by "duplex bogie engines, introduced in 1869, having two engines, united by a tender common to the two, and hinged at the centre." He goes on to say that these are called Fairlie engines, after the name of their designer. The Fairlie engines as used on the Mexican Railway certainly do not agree with this description, nor does this description agree with the usually accepted type of engine known as the "Fairlie." The Fairlie engine consists of a special type of boiler carried on bogies, one at each end. These bogies have either four or six wheels, as the case may be; each bogie is fitted with steam cylinders and gear complete, and all the wheels are coupled. The boiler has a smoke-box at each end, and is fitted with fire-boxes in the centre, being fired from the side. The steam pipes from the boiler to the "steam" bogies are flexible, to allow the bogies to take the curves. The water is carried in side tanks, and the fuel on the top of the boiler and at the side. The author will observe that there is no central pivot and no tender; the engine is a tank engine; and that the whole of its weight is good for adhesion. The Fairlie engines at work on the Mexican Railway weigh in order about 92 tons. The total wheel base is 32 feet 5 inches, and the rigid wheel base of the bogie is 8 feet 3 inches.

Chapter iii. includes narrow gauge railways, as well as the Fell, Rigi, Pilatus, and Abt mountain railways. The use of a narrow gauge railway in place of the standard gauge is due to questions of cost of construction by diminishing the width of the line, and also enabling sharper curves to be adopted. Narrow gauge railways now in use were years ago of ample capacity for the traffic then available, but are now a continual source of trouble where the traffic has increased beyond their capacity. In some cases, where an increase of gauge is impossible owing to the cost, the rolling stock has to be designed to suit the abnormal requirements, and the locomotives recently designed have to be made to suit the conditions, and are working under adverse conditions from a locomotive engineer's point of view. The cost of a break of gauge is a serious matter, involving as it does the transshipment of passengers and goods, as well as two classes of rolling stock. In India, for instance, the metre gauge has given place to the broad gauge of 5 feet 6 inches in many cases, in order to obtain through communication without break of gauge. The author gives an excellent description of the various mountain railways named, and they are without doubt monuments of engineering daring and skill.

In chapter iv. an excellent description is given of the piercing of the Alps. To the rivalry of European Powers, each anxious to command a route, are due the several Alpine tunnels; from the design and execution of the Mont Cenis tunnel to the more recent schemes west of the St. Gothard. Had the author told us a little more about the difficulties encountered, he would have added considerably to the interest.

Tunnels under the Alps naturally give place to subaqueous tunnels in the sequence of subject-matter in the volume. The Mersey and Severn tunnels are described, and the tremendous difficulties encountered in the execution of the latter undertaking are pointed out. We also find a description of several subaqueous tunnels in the States, including the Sarnia tunnel recently opened under the St. Clair river, to connect the Grand Trunk Railway of Canada at Sarnia with the United States Railways at Port Huron. The chapter closes with an account of the proposed Channel Tunnel.

The progress and principles of modern bridge construction are treated in chapter vi. This gives a good account of the great advance made during the last fifty years in this important branch of engineering. Wrought-iron gradually superseded cast-iron in bridge construction, and steel has again superseded it. The manufacture of steel has now reached a stage in which there are no uncertainties in its quality. The earliest instance of the adoption of steel for a bridge is the St. Louis Bridge, over the Mississippi, constructed in 1867–74, and the most recent example is, of course, the cantilever bridge, with two spans of 1700 feet, over the Firth of Forth. The author gives the great Indian bridge over the Rori branch of the River Indus, at Sukkur, very little notice, and does scant justice to this "achievement in engineering," certainly a monument to its designer. Designed by Sir Alexander M. Rendel, K.C.I.E., M.Inst.C.E., and built by, and erected on the works of Messrs. Westwood, Baillie, and Co, of London, this bridge was taken to pieces and shipped to India, where it was re-erected. The chapter closes with an account of the proposed bridge over the Channel.

Submarine mining and blasting are treated in the chapter that follows. This chapter is interesting mainly owing to a detailed description of the operations for improving the entrance to New York Harbour by the removal of the obstructions at Hell Gate and Hallett's reef. With reference to the explosion at the latter site, it is interesting to observe that the earth-wave produced was carefully recorded at various places, and the rate of transmission of the shock was found to be more rapid and more uniform when the shock passed northwards through rock, than when it passed through drift in an easterly direction. In travelling through drift, it reached Goat Island, a distance of 145 miles, in 59 seconds, and Harvard College Observatory, 182⅜ miles, in 3 minutes 40 seconds; and in travelling through rock, it reached West Point, 42½ miles distant, in 11 seconds, and Litchfield Observatory, 174⅛ miles away, in 45½ seconds.

Chapters ix. to xv. deal with that branch of engineering which may be roughly included under the title of "Harbours and Docks." In a previous work by the author, bearing this title, and reviewed in these columns, this subject was amply dealt with, and it will now be sufficient to state that the present chapters are well up to the standard of excellence of his previous work. We find an interesting description of the Manchester Ship Canal works in these chapters—a work rapidly nearing completion, and one which, if successful, will be the forerunner of many similar works in this country. An illustration is given, showing the progress of the works forming the Eastham Locks, viewed from the Eastham end. This illustration gives a very good idea of the magnitude of the undertaking. Another Manchester undertaking occupies considerable space in this work, viz. the Manchester waterworks, and more particularly the Thirlmere scheme. The author tells us that the eventual maximum daily supply of 50 million gallons of water will be conveyed to Manchester by an aqueduct, or conduit, about 100 miles long. Another similar undertaking is also discussed; in the Liverpool Vyrnwy scheme we find how engineers have solved the difficulty of getting a pure water supply for that city.

The volume concludes with an account of the Eddystone Lighthouse and the Eiffel Tower.

The frontispiece is a portrait of Robert Stephenson, a very appropriate one for such a work. His name will ever be associated with the development of railways, as the author remarks; and he might also have pointed out that the railway has been in many cases the reason for many "achievements in engineering" being called into existence.

Taken as a whole, this work is a very interesting one. It is well written, and the author may be congratulated on having succeeded in his endeavour to describe briefly some of the principal engineering works carried out, at home and abroad, within the last fifty years. The book is well printed, and the illustrations are excellent, although there might perhaps have been more of them, considering that the general reader has to be provided for. N. J. L.

GEOLOGICAL EXCURSIONS.

Geologists' Association: a Record of Excursions made between 1860 *and* 1890. Edited by Thomas Vincent Holmes, F.G.S., and C. Davies Sherborn, F.G.S. (London: E. Stanford, 1891.)

THE Geologists' Association began its useful career of work more than thirty years since. It has stimulated—more, perhaps, than any other body—a real interest in geology among those who live in and about London, because it has enabled students, still near the outset of their work, not only to meet for mutual help and encouragement, but also to be aided by those of repute in science. Of its meetings, not the least pleasant and useful are the excursions. At first these were made generally once a week, so long as weather permitted, and they occupied a Saturday afternoon or at most a single day. Then an occasional journey of longer duration was attempted; now it is usual to undertake excursions, lasting two or three days, at Easter and Whitsuntide, and one of a week or more during the summer holidays. Before each excursion a flysheet is issued to the members with a brief description of the geology of the locality, illustrated by diagrams and containing references to books and papers. Afterwards, a report of the excursion is inserted in the Proceedings of the Association. It was a happy thought to collect together in one volume these scattered notices, for they give succinct descriptions of almost all the localities of geological interest readily reached from London, so grouped as to be conveniently accessible. Thus the student, instead of having to compile for himself, from books or maps, a plan of campaign, whether for an afternoon or for a longer time, finds everything arranged ready to his hand, and is directed to the sections best worth visiting. These diagrams and reports possess a further value, that they frequently record sections which can be no longer examined, because they now either are overgrown by vegetation, or have been removed in quarrying. The work therefore is a geological guide-book of an exceptional and a very convenient character to a large district around London, and to several other localities of special interest in England.

The plan which has been followed in compiling the volume is stated in the preface. The excursions are grouped, as far as possible, within county boundaries; where more than one visit has been paid to any place, the editors have "either suppressed the shorter, and retained the fuller, or given from each account that which is not to be found elsewhere." The reports have been condensed by the excision of matters of general or merely temporary interest, and although references are made to all excursions up to the year 1890, no reports are given of later dates than 1884, because since 1885 it has been customary to print all these in the November number of the Proceedings, so that they can be easily consulted.

The thanks of the Association—indeed of a wider circle of geologists—are due to the editors for the pains which they have taken in discharging a very laborious duty. It seems almost ungracious to criticize, and to do it effectively would require encyclopædic knowledge; but we think that, though it may have been "impossible to send each report to the original reporter for revision," it would have been prudent to submit it to someone with a special knowledge of each district. These reports occasionally contain *obiter dicta*, or the crude speculations of members who are better acquainted with their own locality than with the principles of the science. Hence obsolete notions are preserved like flies in amber: these may perplex, but they cannot help the beginner. By way of testing the results of the editors' method, we have examined the reports of two or three districts with which we are specially familiar. The statement on p. 203 about the section at Roswell Pit, near Ely, is misleading. The natural interpretation of its words would be that the Kimeridge clay formed a part of the great erratic. This, in reality, consists of Cretaceous rocks, the Jurassic clay being *in situ*. On p. 216, the sentence "at the base, as at the top of the Gault," should have been "below the base, as above the top." Again, the clay beneath the neighbouring Upware limestone, now admitted to be Coral rag, cannot well be Ampthill clay, and we are not aware of any evidence in favour of this view. Again, the account of Charnwood Forest needs correction. At p. 463 a statement is quoted, which was published without due authority, and has been recalled by the author. On pp. 465 and 466 the suggestion that the Charnwood Forest rocks "ought to be called Laurentian" should have been cancelled. It was groundless, even as Laurentian was defined in 1875: it is absurd now. All reference to the "Archæan Petrology" of Prof. Ansted might well have been omitted. On p. 472, Peldar Tor is twice misprinted Peddar Tor. We know of no ground for the statement, on p. 473, that "the quartz [in the rocks of this neighbourhood] appears to be of subsequent formation." Doubtless similar defects could be pointed out by others; indeed, our own list is not quite exhausted, but we have no desire to carp at a book on which so much labour has been bestowed, and prefer to welcome it as a valuable addition to British geology, which will be indispensable to all students who live in the neighbourhood of the metropolis. T. G. B.

OUR BOOK SHELF.

Across East African Glaciers: An Account of the First Ascent of Kilimanjaro. By Dr. Hans Meyer. Translated from the German by E. H. S. Calder. (London: George Philip and Son, 1891.)

LONG before he thought of exploring any part of Africa, Dr. Meyer was an experienced and enthusiastic traveller. The idea of undertaking explorations in "the Dark Continent" was suggested to him by the fact that while the German colonial possessions in the west of Africa had been thoroughly investigated under Government supervision, and at the Government expense, those in the East had been left to the more limited resources of commercial companies. It occurred to Dr. Meyer that he might do good service to his countrymen by devoting himself to the task which the German Government seemed so unwilling to undertake. Accordingly, in 1886, he began to make preparations for the accomplishment of his plan and since that time he has organized no fewer than three important expeditions, in the third of which he succeeded in reaching the top of Kilimanjaro. It is this third expedition of which an account is given in the present work. The broad results of the journey were soon made known; but of course it is only from the explorer's full narrative that an adequate idea can be formed of the interest and importance of his achievements. The mountain mass of Kilimanjaro towers up to a height of nearly 20,000 feet, and Dr. Meyer describes well the feelings with which he saw it after his arduous march across the steppes. "It was a picture," he says, "full of contrasts—here the swelling heat of the equator, the naked negro, and the palm-trees of Taveta—yonder, arctic snow and ice, and an atmosphere of god-like repose, where once was the angry turmoil of a fiery volcano." The story of the ascent is told most vividly, and there are few readers who will not sympathize with the delight with which he speaks of the moment when he set foot on the culminating peak. Although the record of his experiences at Kilimanjaro forms the centre of the book, he has much to say about what he saw both on his way to the mountain and on his way back; and in appendices various writers present classifications of his collections, and the conclusions at which they have arrived in working out his astronomical and meteorological data. The book is admirably translated, and its value is greatly increased by illustrations and maps.

Chemistry in Space. From Prof. T. H. van 't Hoff's "Dix Années dans l'Histoire d'une Théorie." Translated and Edited by J. E. Marsh, B.A. (Oxford: Clarendon Press, 1891.)

WE have already reviewed the monograph of which this is a translation (NATURE, vol. xxxvii. p. 121), and need not therefore, at present, say anything of the subject with which it deals. The translator has done his work carefully, and "the invaluable assistance and advice" of the author have enabled him to make his rendering "a considerable extension of the French edition." Mr. Marsh advises those to whom the question is new to leave the first chapter till the end, as it contains a translation of the earliest memoirs on the subject, and the ideas are incompletely developed, obscure, and sometimes erroneous.

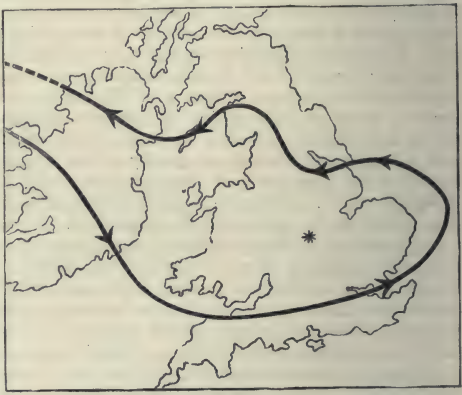
LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Erratic Track of a Barometric Depression.

THE singular course of the cyclonic system which has, during the week terminating on May 29, circulated round and across the British Isles, deserves more attention than can be thus early given to it. I wish here, with your permission, first, to describe the path of its centre as correctly as can be done with the data at present in my hands, mentioning at the same time the principal modifications of the isobars and of the weather in the neighbourhood of the centre; secondly, to mention some remarkable facts in relation to the upper currents as observed by myself in its neighbourhood; and finally, to indicate the nature of those questions an examination of which will, I believe, in the instance before me, prove to be of most scientific value.

(1) The accompanying chart shows the course of the centre of depression, so far as we have yet been able to follow its track, the arrow-heads marking the position at 6 p.m. of each day. At 8 a.m. of the 23rd, the centre appears to have lain about 60 miles to the west of Erris Head, with a barometrical pressure of a little below 29·4. By 6 p.m. it had advanced south-eastwards into Connaught with a velocity of 6·5 English miles per hour, and by 8 a.m. of the 24th to a little west of St. Anne's Head. During the above period the depression was elongating itself, the position of its major axis changing from N.W.-S.E. into W.-E. The weather in the meantime was becoming rainy in the English Channel and home counties, while continuing fair in the north. At 6 p.m. of the 24th the eastward elongation of the whole system had become very marked; and at this hour the centre lay over the mouth of the Thames, after a somewhat lengthened thunder-storm over London, Woolwich, &c. The velocity of transit during the twenty-four hours had been 22 miles per hour, and the path of the centre was beginning to curve towards the left. By the morning of the 25th the centre had advanced to N.N.E., and lay about 53° 2′ N. lat., 0° 24′ W. long., with wet and cloudy weather over our eastern and midland districts. By 6 p.m. of that day the centre had begun to move slightly to the westward, having moved during the twenty-four hours with a velocity of 10 miles per hour. By the morning of the 26th the centre was near the mouth of the Humber, rainfall continuing over the north-east and north midland counties; at 6 p.m. of that day the centre lay over north-west Lincoln, having moved only with a velocity of about 3·8 m. per hour. The centre now moved to the neighbourhood of the Solway, with a velocity of about 10 miles per hour, and on the evening of the 27th began to recurve again a little to the left, the system at the same time becoming more circular in form, and the central pressures slightly decreasing. During this day rain and cloud prevailed on the west of the system, while in its rear there were some scattered thunder and hail showers of the type prevalent in summer in the rear of cyclonic systems travelling to north-east. At 6 p.m. on the following day the central area had passed into Ulster, with a velocity of 5·5 miles per hour. The thunderstorms in the rear were on that day more pronounced. During the following night the centre travelled with increased velocity across Donegal to the Atlantic, and by 6 p.m. of the 29th the exterior isobars of the system had almost left our shores, finer weather setting in over Great Britain generally.



(2) The point marked with an asterisk on the chart marks the position of the writer during the progress of the depression, a position of vantage for the observation of upper currents, the value of which was much diminished by the predominant thickness of low cloud, and by the fact that there was little moonlight. Over the Midlands outlying threads of "cirro-filum" advanced with great velocity from north-north-west at noon of the 23rd, soon after which a great sheet of frozen veil-cloud rapidly overspread the sky, the exterior edge of which soon disappeared over the north-east horizon. A brilliant solar halo was completely eclipsed before 5 p.m. Meanwhile the lower cloud-current backed from south-west to south. At 7.32 p.m. there was a squall of wind from south-east with rain, and a "jump" in the barograph. About noon of the following day, when the centre was about 118 miles to the south-south-west a glimpse of the upper clouds was obtained; they were then moving from south. Further opportunities of observation were obtained in the

evening, which showed that the upper current had changed to south-east. No observations could be made during the two wet days which followed; but early in the morning of the 27th, when the centre was about 100 miles to the north, true cirri were observed moving slowly from north-east. These soon disappeared; but at 6 p.m. of the same day an important change took place, the bands of ice-cloud moving from south-south-west, from which point, or from a little west of it, the belts have continued to travel up to the time of my writing this, the lines being nearly parallel to the isobars, and to the general direction of the surface winds, and precisely resembling in character the stripes seen in most cases travelling from north-north-west when a depression, whose centre has passed a little to the north of the observer, has moved away to north-east.[1]

(3) In an elaborate paper in the Quart. Journ. of the R. Met. Soc. for October 1877, the writer pointed out that in the extreme left-hand segment of an approximately circular cyclone, moving in any direction in the northern temperate latitudes, the movements of the upper currents are by no means analogous to those in the right-hand segment.[2] In the case of cyclones travelling eastwards, the reason of this difference is, I think, now well understood. Owing to the great relative density of the lower atmosphere, attended with low barometric pressure, near the poles, the gradients for westerly currents are far more constant in the upper than in the lower strata of the atmosphere in the regions traversed by extra-tropical cyclones. Over a large number of these cyclones, therefore, many of the isobars in the upper regions of the atmosphere do not form closed curves, but curves somewhat resembling those which, at the earth's surface, accompanying what are popularly termed V-shaped depressions. It is a question of the utmost interest whether, during the periods in which depressions travel to the west, the distribution of gradients in the upper atmosphere is really for the time reversed, and, if so, what can be the causes of so remarkable a change. There is a further question correlated with the above, which deserves more attention than has been given to it. The writer long ago pointed out (Journ. Scot. Met. Soc., vol. iv. pp. 333–335) that in cases of depressions travelling westward across our islands, temperatures at the earth's surface are in general higher over Scandinavia than over France; and a considerable number of instances have occurred since 1875 which have confirmed this conclusion. But in most of these cases an anticyclone has lain to the north-east of us, so that the "gradient force" of the lower strata may have tended to send the depression westwards, in addition to the ascensional force, associated with condensation in the western segment, due to the indraught of relatively warm air from north and north-east. In the instance described in this paper pressure was not particularly high over Scandinavia, during the westward progress of the system, but temperature seems to have been higher, over Sweden at least, than in France.

The Crowing of the Jungle Cock.

IN NATURE (vol. xliii. p. 295) Mr. Henry O. Forbes has a letter commenting on a statement of Mr. Bartlett to the effect that the wild jungle cock does not crow, and testifying that he once heard one. In reply, in the next number of NATURE, it was suggested that the cock heard by Mr. Forbes was a hybrid.

I think that no one who has travelled in the jungles of Burma, during the dry season, can have any doubt that the jungle cock crows; for he cannot fail to have heard them many times.

It so happens that, just after reading Mr. Forbes's letter, I had occasion to travel among the hills which form the watershed between the Irrawaddy and the Sittong rivers. In one region here a large kind of bamboo was seeding, so that the jungle fowl were very numerous, and I heard them crowing in great numbers. I remember one place in particular: the Karens had prepared us a hut in which to sleep just outside of their village, which consisted, like nearly all the villages in these hills, of a single house, each family having its separate room in the common building. "At cock crowing" in the morning we had, close to us, the crowing of the village cocks, and on every side, far and near, the answering crows of multitudes of wild birds. I do not remember ever to have been treated to such a chanticleer concert before.

The idea that these wild cocks were all hybrids is inadmissible, because (1) they were so very numerous, and (2) the country is very sparsely peopled, the villages all being small and far apart, and the greater part of the country still covered with primæval forest.

The crow of the jungle cock is shrill, like that of the smallest breeds of domestic fowl, and is, perhaps, a little less prolonged than that of the average domestic cock; but it can hardly be distinguished from the crow of a small breed of fowl kept by the Karens, some individuals of which so closely resemble the wild fowl that they are used as decoys.

I have several times heard wild fowl cackle, and in this journey, while in the midst of a heavy forest, miles from any human habitation, we came upon a flock of wild fowl cackling, and could tell by the tones that both cocks and hens were cackling. One of the followers being sent with a gun to try and get a shot, some of the birds saw him and flew, whereupon one of the cocks gave the peculiar call which the domestic cock gives when a bird flies over him.

I might add that, among the numerous birds shot in this region, there was one hen which had a pair of spurs about half an inch long.

B. P. CROSS.

Rangoon, May 20.

Cordylophora lacustris.

IT is generally believed that this tube-dwelling Hydrozoa was originally a salt-water animal, and although now found a considerable distance from tidal water, it still dwells in rivers and canals more or less connected with tidal rivers. I have for many years found it in the Chester and Ellesmere Port Canal, growing principally on the shells of the fresh-water mussel, from two to three miles from the tidal river (the Dee). It seems to be a shade-loving animal, as I have always found it under the bridges, and from 4 to 6 feet beneath the surface of the water.

The tubes *only* remain during the winter and early spring, and the animal is fully developed in August and September. It is generally accompanied by *Fredericella sultana*.

Kingsley Lodge, Chester, June 12.

Philosophical Instrument Makers.

I FIND in your paper of June 11 (p. 135) that Messrs. Newton and Co. have been appointed philosophical instrument makers to the Royal Institution of Great Britain. Allow me to state that they are not the only ones, and that I also was appointed on June 1 by the managers of the Royal Institution of Great Britain to be their philosophical instrument maker. I thought that in the interest of the public you should know this fact.

A. HILGER.

The Earthquake of June 7.

THE earthquake of June 7, whose centre seems to have been in the province of Verona, was also perceptible at Basle. The seismometer of the Bernoullianum Observatory registered a horizontal shock at 1h. 47m. 29s. a. Basle mean time, which corresponds to 1h. 17m. 10s. Greenwich mean time.

At Thal, a village east of St. Gall, the shock was strong enough to be felt by several persons.

Basle, June 13. A. RIGGENBACH-BURCKHARDT.

NOTE ON EGYPTIAN IRRIGATION.

IN entering upon any account of Egyptian irrigation it is necessary, at first, to point out that it consists of two very broad subdivisions: (1) the irrigation effected by the Nile flood when there is rich muddy water in abundance for a land thrice as big as Egypt, and when everyone considers it his absolute right to have his fields flooded without the expense or trouble of raising the water artificially; and (2) the irrigation effected by the Nile at its lowest, in those hot months of May and June when the water surface is 20 feet below that of the field, and when it is only by the strictest economy that we can water an area not exceeding one-fourth of the whole of Egypt.

---

[1] These stripes or cirro-filum are so abundant in the rear of most depressions, towards the termination of the inversion disturbances accompanying squalls or thunder-showers, in Europe and the Northern States that it is singularly unfortunate that the statement of an English meteorologist, to the effect that they do not exist, should have found its way into the first edition of Ferrel's "Popular Treatise on the Winds."

[2] See also Ferrel, "Pop. Treat.," § 180; "Modern Meteorology," p. 111 (diagram).

2. *The Irrigation of Old Egypt.*—The first irrigation is the ancient art of Egypt, the culture that, from the days of the Pharaohs, made this little valley the granary of Europe. The products are wheat, barley, beans, maize, and rice. These two last crops require special irrigation. For the growth of wheat, barley, and beans, it is enough to saturate the fields, during high flood, from August to October. The seed is scattered as the waters retreat, and the fields receive neither irrigation nor rain from that time till the harvest is gathered in at the end of April.

3. *Perennial Irrigation.*—The introduction of the second system is due to the sagacity of Mohamed Ali, who saw that the conditions of soil and climate were such as to favour the growth of cotton and sugar-cane, sub-tropical products greatly exceeding the value of cereals. But these crops require irrigation during the months when the Nile is at its lowest, hence a system of deep canals was necessary, and it was in trying to carry out this system in Lower Egypt that the Egyptians got into hopeless difficulties, for the canals got blocked with silt, and it was most difficult to clear them.

4. *The Barrage unused.*—The obvious remedy was to raise the water in the river, and divert it into the canals by a Barrage or dam at the apex of the Delta. Such a work was constructed, at a cost of about two millions sterling; but soon after its completion it cracked in a very alarming way, and, from 1867 to 1883, remained practically useless. The great network of canals continued to be cleared year after year to a depth of about 20 feet below the soil, and for half of each year the *corvée* was constantly employed on them.

5. *Pumping.*—The Egyptian Government had abandoned all hope of again using the Barrage. They had entered into a contract with a private company to irrigate Behera by a system of pumps, at an annual cost of from £50,000 to £60,000; and they were about to come to similar arrangements for the rest of the Delta, at an initial cost of £700,000, and an annual one of £250,000.

6. *Neglect of Drainage.*—Continuous irrigation like that of Lower Egypt requires to be accompanied by drainage, otherwise the land becomes soured and waterlogged. No attention was being paid to this subject in 1883.

7. *State of Upper Egypt.*—The first system of irrigation alluded to above continued to be practised in Upper Egypt. A few very costly bridges had been built to assist it, but little attention was being bestowed on it, and even in years of average Nile flood we found a loss of annual revenue amounting to about £38,000 taking place.

8. *Addition to Area of Egypt.*—Such was the state of affairs when we took charge of the irrigation in 1884. I am frequently asked whether, since then, there has not been a great addition to the cultivated area of Egypt. My reply is in the negative.

The question of extending cultivation into the desert is partly one of displacement of population, chiefly one of level, for above the point that the Nile flood can be brought to reach we must not look for an extension of cultivation. Some goes on—notably to the west of the province of Behera and in the Fayoum; but it is not on a very large scale.

9. *Reclamation of Marshes.*—An extension much more rapid, and of more importance, is in progress along all the north of the Delta, where land is being yearly reclaimed from marsh and lagoon by our drainage operations.

The cultivated and revenue-paying area of Egypt is about five millions of acres. The lagoons in the north cover an area of about 1,280,000 acres. I expect in a very few years to see at least half of this land reclaimed and cultivated.

10. *The Barrage repaired, and the Effect on Lower Egypt.*—What we have done, are doing, and propose to do, then, in future years is as follows:—

First. The Barrage has been completed, and placed in a condition to fulfil its original purpose. From upstream of it are derived three main trunk canals which irrigate the whole Delta, and three smaller canals which irrigate all the country north-east of Cairo and to the south of Zagazig; one of these takes water to Port Said and Suez. The outlay on the Barrage has been, since 1884, about £460,000.

Of the three trunk canals, that on the west had been neglected, and completely filled in with sand. It has been restored, and the system of pumps alluded to in paragraph 5 will, I hope, never be used again.

The canal supplying the East Delta (termed the Tewfikieh Canal) has been entirely made since 1886, at a cost of £372,000.

Practically, the whole summer supply of the Nile is diverted by the Barrage into these canals, and none flows out useless to the sea. The value of the work is this—that so long as there is water in the Nile it is under our control, and, however low the river may fall, the water will get on to the fields, and the great cotton crop will be secured. In former days, during low Nile, the canals were left high and dry, and what water there was flowed out to the sea, useless.

The Barrage has not much increased the area of cultivation, but it has very largely increased that of land bearing double crops—that is, the area producing cotton. It was in 1884 that, by employing temporary measures, we began to use the Barrage. Since then, the average annual yield of cotton has been 333,893 kantars (15,000 tons) greater than in the five years preceding 1884. This represents a value to the country of £835,000 a year, exclusive of the value of cotton-seeds.

11. *Provision for Navigation.*—Secondly. As the abstraction of water renders impossible the river navigation during four or five months every year, two main canals have been selected, one of them roughly parallel to each of the branches of the Nile, and fitted with locks and rendered navigable. This is not yet quite finished. When it is, it will enable laden boats to pass freely between Cairo and Alexandria on one side, and Cairo and Damietta on the other side, at all seasons of the year. Other locks have been built, and obstructions removed, so that navigation has had an impulse given to it throughout the whole Delta.

12. *Drainage Introduced.*—Thirdly. Year by year have been opened out new miles of drainage arteries, and in Behera, Gharbieh, Dakahlieh, Sharkieh in Lower Egypt, and in the Fayoum, large tracts have been reclaimed from salt-marsh, and now yield good crops. The Budget for the current year contains £140,000 for new drainage-works in Lower Egypt. No part of our work has been more appreciated than this, but, unfortunately, the defective system of revenue statistics makes it impossible to say what lands have been reclaimed. The mileage of drains is not less than 1500.

13. *Measures for Improving Irrigation of Upper Egypt.*—Fourthly. I have said, in paragraph 7, that there has been an annual loss of about £38,000 in average years, due to the Nile flood not attaining all the fields of Upper Egypt. In exceptional years this loss has been much greater. Thus, after the very deficient flood of 1877 it amounted to £1,111,880. After 1888 it was about £300,000. If such was the loss of revenue alone, it may be imagined what a heavy calamity was inflicted on the

cultivators. Colonel Ross, Inspector-General of Irrigation, has studied this subject most closely. Even in these deficient years there was water enough in the river if it could only be got on to the land. He has proved that, by a judicious system of canals, sluices, siphons, escapes, weirs, &c., it may be arranged that, even in the worst years, the whole Nile valley shall receive its share of mud-charged water. This involves the construction of no great work like the Barrage (the most expensive does not exceed £45,000), but of a great number of works costing from £5000 to £15,000 each, requiring very careful designing, and built often in remote spots, where construction of any kind is difficult.

These works have been going on now for more than a year. When finished, as I hope they will be in 1893, the whole outlay will be about £600,000. And then, I trust, the lands of Upper Egypt will yield their full crop, however defective may be the Nile flood.

14. *Agricultural Roads.*—Fifthly. A minor subject, and yet one of great value to the country, deserves notice here—namely, the introduction of agricultural roads, This reform is due to Riaz Pasha. Until two years ago. it would have been impossible to take a cart-load of agricultural produce from any one centre of population to another in the Delta. Comparatively few of the canals were adapted for boats, and the one means of transporting cotton to the railway stations or to the river was by camels, which, however well adapted for carrying burdens on the firm sand of the desert, are not suitable for the rich alluvial soil and the sloppy fields of the Nile valley. This is all being changed. The people have willingly accepted a tax never exceeding P.E. 4 or 5 per feddan for one year only, and, with the fund thus raised, a whole network of serviceable roads is being formed sufficiently adapted for this dry climate.

15. *Corvée Abolition.*—The above paragraphs describe generally the improvements that have been brought about in the last seven years. Second to none is the boon that has been conferred on Egypt in the abolition of the *corvée*. Previous to 1885, the whole of the earth-work in the clearance and repairs of canals and embankments was effected by the forced, unpaid, unfed labour of the peasantry. In 1884 this labour amounted to 85,000 men working for 160 days. We were told that this was quite a necessary state of things, that it would be impossible to maintain the irrigation-works otherwise, and that the Egyptian peasant, unlike that of any other country, would not work for wages, and must be forced. We estimated that to redeem this *corvée* and to pay for all this labour would cost £400,000. Nubar Pasha, in the face of the greatest financial difficulty and opposition, managed to give an annual grant of £250,000 for this object. Riaz Pasha, at the end of 1889, found means of granting the remaining £150,000, and in 1890, for the first time perhaps in all history, there was no *corvée* in Egypt.

16. *Canal Legislation.*—When we began work here, we were much hampered by the want of any canal legislation, there being no law corresponding to what is found in India, Italy, and elsewhere, treating of the many conflicting questions connected with irrigation. After three years' discussion, a very useful Canal Act now exists, and the only misfortune is that it is not binding on residents of foreign nationality.

17. *Storage of Nile Water.*—Lastly, as regards our programme for the future, there is abundance to do in carrying out, year by year, solid unpretending reforms; but, besides these, a very large question is coming to the front. The restoration of the Barrage placed at our disposal all the water of low Nile, but the increase in the area irrigated outruns the increase in the water available, and we have to look for means of storing the surplus volume of the flood, and utilizing it when the river is low.

There are two ways in which this may probably be done. The first, which is connected with the name of an ingenious American gentleman, Mr. Cope Whitehouse, is to divert a portion of the flood into a great natural depression existing west of the Nile valley, and there to form a storage reservoir, to be drawn upon as the water in the river decreases. This has been examined and found feasible, but the expense, probably 1½ millions sterling, is against it. The alternative project is to pond up water in the valley of the river itself above Assouan. This project is being studied at present. There can be hardly any further extension of the cotton cultivation if one or the other of these schemes is not executed. There is room enough in the country to employ both.

Colin Scott Moncrieff,
Under-Secretary of State, Public Works Department.

Cairo, March 5, 1891.

THE SECOND ORNITHOLOGICAL CONGRESS.

A FULL report of the proceedings of this important Congress can only be obtained when the official *Comptes rendus* are published, for the officers of one section were unable to attend the meetings of the other sections owing to the fact that all four sections sat at one and the same time. This is the only complaint we have to make concerning the recent proceedings, but as it affects the future of these useful reunions, we feel compelled to make our protest, because, by the simultaneous session of all the sections of a Congress, no man, however interested in the subjects under discussion, can hear all that he wishes to hear; the visitor has to choose between two meetings, both of which probably possess for him an equal interest. It must be obvious to everyone who had the privilege of attending the second Ornithological Congress that a great gathering of specialists such as that which took place last month must require more time than three days to discuss such varied problems as were placed before them at the recent meeting.

The city of Budapest was happily chosen as the meeting-place of the Congress, and it may well be questioned whether there is any country in the world that could have offered so many attractions to the ornithologist as Hungary. The hospitality of the Hungarians is proverbial, the accommodation in the beautiful capital is unlimited, and access thereto is easy. After an enjoyable trip down the Danube from Vienna, the travellers found themselves at the opening *conversazione* of the Congress, which was celebrated in the Grand Hotel "Hungaria." Here the Hungarian Committee had assembled with all the members of the Congress to welcome the guests, and the inaugural banquet served as a pleasant medium for the introduction of the strangers. On May 17 the first general meeting of the Congress took place in the sumptuous theatre of the Hungarian National Museum. After some words of welcome from the Burgomaster of Budapest, the officers for the Congress were chosen as follows:—Honorary Presidents: Count Bethlen, Minister of Agriculture; Count A. Csáky, Minister of Public Instruction; Mr. B. Kállay, Minister of Finance. Presidents: Prof. Victor Fatio (Geneva) and Mr. Otto Herman, M.P. Vice-Presidents: Dr. Rudolph Blasius (Brunswick), Prof. S. Brusina (Agram), Prof. R. Collett (Christiania), Mr. J. de Csató (Budapest), Dr. Otto Finsch (Bremen), Major Alex. von Homeyer (Greifswald), Dr. A. B. Meyer (Dresden), Dr. E. von Middendorf (Livonia), Dr. Emil Oustalet (Paris), Dr. Bowdler Sharpe (British Museum), Mr. E. von Szalay (Budapest), Victor Ritter Tschusi von Schmidhoffen (Hallein). General Secretary: Dr. G. von Horváth. Secretaries: Mr. E. Chernel von Chernelháza, Dr. A. Lendl, Dr. L. Lorenz von Liburnau, Dr. A. Lovassy, Dr. J. von Madarász, Mr. O. Reiser, Prof. G. Szikla. Hon. Secretaries: Mr. E. de Gaál, Mr. B. de Lipthay, Mr. J. d'Ottlik. Quæstor: Mr. J. von

Xántus. After preliminary reports, Major Alex. von Homeyer gave his reminiscences of travel in West Africa some years ago, and his imitations of the notes of African birds were strikingly rendered. Four different sections of the Congress were appointed, the names of the different delegates from foreign countries were read out, as well as letters of apology for their absence from several naturalists, Prof. Fürbringer, Baron de Selys Longchamps, and others.

The officers of the different sections were constituted as follows:—(1) Systematic Section: Presidents, Dr. Bowdler Sharpe (London) and Prof. Claus (Vienna); Vice-Presidents, Dr. A. Reichenow (Berlin) and Mr. C. G. Danford (Siebenburgen). (2) Biology and Oology: President, Dr. Rudolph Blasius. (3) Avigeographia: President, Dr. Palacky (Prag). (4) Economic Ornithology: President, Major Alex. von Homeyer.

On the afternoon of May 17 many of the members of the Congress ascended the Blocksberg, to enjoy a view of the city of Budapest and the Danube flowing below—a view not to be surpassed in beauty and interest in any country.

On Monday, May 18, the Systematic Section met in the lecture-theatre of the Polytechnicum, which was placed at the disposal of the Congress by Prof. Szabo, whose work is well known and appreciated in Great Britain. Papers were read by Prof. Klug, on some points in the anatomy of the stomach in birds, and by Dr. Bowdler Sharpe on the classification of birds, the latter lecture being illustrated by several large diagrams and a wax model of the phylogenetic tree, in which Prof. Fürbringer traces the evolution of birds from a reptilian stock. The remainder of the work of the Systematic Section consisted in the passing of the rules of nomenclature, as put forward by a committee consisting of Prof. Möbius, Dr. A. Reichenow, Count von Berlepoch, Dr. A. B. Meyer, and Dr. W. Blasius. The recommendations of this committee were adopted almost in their entirety by the meeting, after a two-days' discussion, notwithstanding some protests of Dr. Sharpe, and Mr. Büttikofer of the Royal Museum of Leyden, who found themselves in a hopeless minority. The chief points carried were: the adoption of the 10th instead of the 12th edition of the "Systema Naturæ" of Linnæus, the recognition of trinomial names in certain cases, and the adoption of names, even faulty in construction or misspelt, with all the consequences. The tone of the report, however, is so moderate, and exhibits so much consideration for the methods of other ornithologists, that it ought to be possible now to arrive at a definite conclusion for European usage at least; and then it would be easy to assimilate the American and European methods of nomenclature.

In the afternoon of the 18th, the Congress met in the Museum, and Dr. Otto Herman, M.P., gave an account of the distribution of birds in Hungary, and explained the collections which had been made specially for the Congress. These consisted of beautifully mounted cases of Hungarian birds with nests and natural surroundings: some very rare species were included in the collection, which was the work of four ornithologists—Dr. O. Herman, M.P., Dr. Julius von Madarász, Mr. Chernel, and Prof. Szikla. These gentlemen had each occupied a station in different parts of Hungary, and had not only collected the series of birds exhibited, but had also made exact observations on migration and distribution. The Hungarian National Museum is a very fine building, and contains a collection which fairly surprised most of the visitors, the series of native birds being especially complete. Large groups of Laemmergeiers, Sea Eagles, Ospreys, &c., with their nests, eggs, and young birds, are to be seen in the Bird-galleries, and these are principally the work of a well-known Hungarian ornithologist, Dr. J. von Madarász. The collection of Mammalia also comprises some great rarities, and the whole Museum teems with specimens procured by the veteran explorer, Mr. J. von Xántus, whose labours in Lower California and Central America, as well as in Borneo and the Sunda Islands, are also widely known. The Museum likewise contains a fine series of insects, especially Coleoptera, which were shown with much natural pride by Dr. Frivaldszky, who is responsible for the beautiful arrangement of the latter groups. The afternoon closed with an adjournment to the Hungarian Academy of Sciences, where Prof. Robert Collett read a paper on Arctic Bird-life before a crowded audience; and the evening concluded with a banquet at the "Archiduc Stephan" Hotel.

On Tuesday the debate on nomenclature was continued; and in the afternoon the Congress assembled on St. Margaret's Island, which forms a most delightful summer retreat for the inhabitants of Budapest, with its dozens of nightingales, its ruined cloisters, and its sulphur springs.

On Wednesday, the 20th, the general meeting of the Congress was held to receive the reports of the different sections and committees, and the business was concluded. A farewell banquet took place in the evening, and the second Ornithological Congress came to an end.

Next day the members were scattered in different directions—some to their homes, some to join one of the pre-arranged excursions. These were three in number—one to the Hanság marshes and Fertö, a second to the Platten-See, and a third to the districts of the Drave. Of the first excursion, in which the writer took part, he can only say that, under the direction of Dr. von Madarász, the members of the Congress who accompanied it underwent a never-to-be-forgotten experience. The species of birds observed were mostly those unknown to an English naturalist, and the hospitality dispensed by Prince Esterhazy, Baron von Berg, and Count Széchenyi, is not likely to disappear from the memory of those who had the good fortune to partake of it.

THE IMPERIAL PHYSICAL AND TECHNICAL INSTITUTION AT BERLIN.

THE Imperial Physical and Technical Institution which was founded in 1887 at Charlottenburg, near Berlin, under the auspices of the German Government, has now been for some time in active operation, and recently there has been issued by the executive Director, Dr. L. Loewenherz, a Report on the work of the Institution up to the end of last year.

It may be remembered that the Institution has two main objects in view: first, that of physical and technical research appropriate to the practical development of manufacture—researches for instance as to the qualities of metals and materials and as to methods of construction and measurement; the second object being that of fundamental research in theoretical problems in physics, and the testing of all kinds of measuring apparatus applicable for use in science, art, and manufacture. It appears to undertake, therefore, investigations and verifications similar to those undertaken in this country by the Board of Trade, or at the Kew Observatory; and, in France, by the Bureau International des Poids et Mesures. Its staff includes (exclusive of the clerical staff) a President, nominated by the Reichstag; a Director, with a Committee of seven members; seven scientific officers in the department of research; four technical assistants, and several mechanics and machinists.

From time to time, as new methods of testing are adopted, or as fresh work is undertaken, explanatory papers are issued by the responsible officers of the Institution (printed by Julius Springer, Berlin); and the following papers have, amongst others, been already issued:—Karl Scheel, H. F. Wiebe, and Alfr. Böttcher, on meteorological measurements; Dr. K. Feussner and Dr. St. Lindeck, on electrical measurements; Dr. O. Lummer and Dr. E. Brodhun, on optical measurements, including photometry; Dr. F. Foerster and Dr. F. Milius, on chemical analysis of glass.

We gather from the Director's Report above referred to, that the Institution has provided itself with fundamental standards of length and mass; with primary thermometers and barometers; with electrical standards of resistance, current, and pressure; and with apparatus for testing the flashing point of petroleum and inflammable liquids. Its metrological work for the public has included the proving of clinical thermometers, pyrometers, aneroid barometers, manometers, alcohol thermometers for low temperature, and thermometers for chemical research.

In October 1888, the official testing of thermometers was transferred from the Normal Aichungs Commission at Berlin to the Imperial Institution, and all thermometers are still tested on the basis of the regulations laid down by the Commission on November 10, 1885; excepting that, in place of basing the errors of scientific thermometers on a mercurial thermometer, thermometer readings are now reduced to the more accurate scale of the air-thermometer or hydrogen-thermometer.

The use of thermometers for determining pressures, or altitudes, &c., on the occasion of journeys of exploration, &c., seems of late to have increased, for many such have been already presented for examination at the Institution. If the thermometers are made of Jena glass (or of other hard thermometer glass), it would appear to be possible to ascertain pressures with but little trouble to ± 0·25 millimetre. The necessity for using proper glass is shown in an experiment carried out at the Institution with two thermometers, Nos. 42 and 43, made of ordinary Thuringian and crystal glass. On September 7, 1888, the corrections of these thermometers at 87° C. were found to be—

No. 42, $-0^\circ{\cdot}05$; No. 43, $-0^\circ{\cdot}24$ C.

The thermometers were then heated for 15 minutes to a temperature of 100° C.; they were then allowed to cool, and subsequently retested on September 10, when their errors were found to be—

No. 42, $+0^\circ{\cdot}08$; No. 43, $-0^\circ{\cdot}09$ C.

Such variation in the reading of a thermometer after its exposure to a high temperature would unfit it for use in the exact determination of pressures or altitudes.

With reference to the testing of various sorts of glass Dr. F. Milius points out that Weber's process, generally made use of, and which consists in exposing the body to be examined to an atmosphere of muriatic acid vapour for a space of twenty-four hours, is not always trustworthy. Thus, according to the quality of the glass, it appears to be covered more or less, after exposure to the acid vapour, by a thick rime (or hoar frost); and that although the experienced observer finds Weber's method tolerably certain, yet the less experienced observer may sometimes be left in doubt, particularly where rough surfaces are treated, as to whether the rime exists or not; Dr. Milius therefore proposes an optical form of test other than that of the muriatic acid test, as is explained at length in his paper.

Dr. Milius, in conjunction with Dr. F. Foerster, has also investigated the solubility, in water, of potash and soda glass, particularly with reference to Schott's experiments as to the capacity of potash water-glass for absorbing water without losing its vitreous quality. This latter fact can be ascertained by keeping pulverized water-glass under water, when, as in the case of hydraulic cement, a hardening of the paste begins to take place. This process is connected with a development of heat; in the case of water-glass in which there was one atom of potash to three of silicic acid it was observed at the Institution that within a quarter of an hour the moistened matter had been heated 10° Centigrade, and it became hard in one day; if the proportion of silicic acid is larger, the glass requires from two to three days for solidification. Their researches appear to show that for purposes connected with mercurial electrical standards, the glass used should be very little soluble in water and acids; hard glass, for instance, which had a base of soda, and not potash, being little hygrometric.

In the important field of electrical measurements, the Institution appears also to be doing good work. It is preparing to undertake the verification of all kinds of apparatus; including voltmeters, ammeters, meters for the measurement of power and efficiency, galvanometers, and resistance coils.

In the field of practical photometry we have to compare the intensities of different sources of light as experienced by the eye; but unfortunately we have not, even for commercial purposes, any satisfactory method by which intercomparisons may be made between the relative intensities of coal-gas, electric and oil lights respectively. In practical photometry much is being done in this country by Abney, Vernon-Harcourt, Chaney, and others, as well as by Lummer, Brodhun, and others in Germany, but as yet no standard photometer has been produced. The standard light is still also the ancient "sperm-candle," and the method of comparison is still the old-fashioned "grease-spot" Bunsen photometer more or less modified. The German authorities appear to be fully alive to the necessity of improvement in this field of technical research; and have investigated M. Violle's incandescent platinum-standard of light, and also the Hefner lamp and Aubert's apparatus; and for electrical light purposes they have followed a form of standard glow lamp.

Among the papers above referred to, we notice also one by Dr. Loewenherz, on the testing of tuning-forks. The Institution undertakes the testing of tuning-forks, on payment of a small fee, the object of the examination being to ascertain the correctness of the height of the tone of the fork in terms of an international diapason; or the number of the vibrations of the fork per second, at the temperature of 15° Centigrade, the pitch of the note A being fixed at 435 entire vibrations per second, or 870 half or single vibrations according to the French method of counting. Tuning-forks sent to the Institution for examination are required to be constructed in accordance with conditions laid down by the Institution. Unity of pitch is of fundamental importance in music and in the construction of musical instruments, and it is to be desired that some authoritative testing of tuning-forks might be similarly undertaken in this country.

In metallurgy the work of the chemical laboratories of the Institution does not appear to be extensive; it has included more particularly analyses of the metals platinum, cadmium, and rhodium. In the Physical Laboratory, measuring instruments of precision for workshop use, such as speed and power indicators, screw-thread gauges, have also been examined by the Institution; and its geodetical work has included the verification of instruments of precision for General Schreiber, of the Imperial Prussian Land Survey. The department has undertaken also the verification of polariscopes, lenses, prisms, and other optical instruments, to a limited extent.

The above observations may serve to show that the Institution is alike prepared to verify a standard—as a measurer of electrical resistance—with the utmost accuracy, or to test an instrument for common purposes—as a gas meter. How far the Institution may be self-supporting is not stated in the Director's Report; but as the demands for verification work of this kind are largely voluntary, it would appear to be evident that the excellent staff of the Institution could not be maintained unless it received valuable support from the State.

CRYSTALLIZATION.[1]

THERE is something very fascinating about crystals. It is not merely the intrinsic beauty of their forms, their picturesque grouping, and the play of light upon their faces, but there is a feeling of wonder at the power of Nature, which causes substances, in passing from the fluid to the solid state, to assume regular shapes bounded by plane faces, each substance with its own set of forms, and its faces arranged with characteristic symmetry: some, like alum, in perfect octahedra; others, like blue vitriol, in shapes which are regularly oblique. It is this power of Nature which is the subject of this discourse. I hope to show that crystalline forms, with all their regularity and symmetry, are the outcome of the accepted principles of mechanics. I shall invoke no peculiar force, but only such as we are already familiar with in other facts of Nature. I shall call in only the same force that produces the rise of a liquid in a capillary tube and the surface-tension at the boundary of two substances which do not mix. Whether this force be different from gravity I need not stop to inquire, for any attractive force which for small masses, such as we suppose the molecules of matter to be, is only sensible at insensible distances is sufficient for my purpose.

We know that the external forms of crystals are intimately connected with their internal structure. This is betrayed by the cleavages with which in mica and selenite everybody is familiar, and which extend to the minutest parts, as is seen in the tiny rhombs which form the dust of crushed calcite. It is better marked by the optical properties, single and double refraction, and the effects of crystals on polarized light. These familiar facts lead up to the thought that it is really the internal structure which determines the external form. As a starting-point for considering that structure, I assume that crystalline matter is made up of molecules, and that, whereas in the fluid state the molecules move about amongst themselves, in the solid state they have little freedom. They are always within the range of each other's influence, and do not change their relative places. Nevertheless, these molecules are in constant and very rapid motion. Not only will they communicate heat to colder bodies in contact with them, but they are always radiating, which means producing waves in the ether at the rate of many billions in a second. We are sure that they have a great deal of energy, and, if they cannot move far, they must have very rapid vibratory motions. It is reasonable to suppose that the parts of each molecule swing, backwards and forwards, through, or about, the centre of mass of the molecule. The average distances to which the parts swing will determine the average dimensions of the molecule, the average space it occupies.

Dalton fancied he had proved that the atoms of the chemical elements must be spherical, because there was no assignable cause why they should be longer in one dimension than another. I rather invert his argument. I see no reason why the excursions of the parts of a molecule from the centre of mass should be equal in all directions, and therefore assume, as the most general case, that these excursions are unequal in different directions. And, since the movements must be symmetrical with reference to the centre of mass of the molecule, they will in general be included within an ellipsoid, of which the centre is the centre of mass.

Here I may, perhaps, guard against a misconception. We chemists are familiar with the notion of complex molecules; and most of us figure to ourselves a molecule of common salt as consisting of an atom of sodium and one of chlorine held together by some sort of force, and it may be imagined that these atoms are the parts of the molecules which I have in mind. That, however, is not my notion. I am paradoxical enough to disbelieve altogether in the existence of either sodium or chlorine in common salt. Were my audience a less philosophical one I could imagine I heard the retort from many a lip: "Why, you can get sodium and chlorine out of it, and you can make it out of sodium and chlorine!" But no, you cannot get either sodium or chlorine out of common salt without first adding something which seems to me of the essence of the matter. You can get neither sodium nor chlorine from it without adding energy; nor can you make it out of these elements without subtracting energy. My point is that energy is of the essence of the molecule. Each kind of molecule has its own motion; and in this I think most physicists will agree with me. Chemists will agree with me in thinking that all the molecules of the same element, or compound, are alike in mass, and in the space they occupy at a given temperature and pressure. The only remaining assumption I make is that the form of the ellipsoid—the relative lengths of its axes—is *on the average* the same for all the molecules of the same substance. This implies that the distances of the excursions of the parts of the molecule depend on its constitution, and are, on the average, the same in similarly constituted molecules under similar circumstances.

I have come to the end of my postulates. I hope they are such as you will readily concede. I want you to conceive of each molecule as having its parts in extremely rapid vibration, so that it occupies a larger space than it would occupy if its parts were at rest; and that the excursions of the parts about the centre of mass are on the average, at a given temperature and pressure, comprised within a certain ellipsoid; that the dimensions of this ellipsoid are the same for all molecules of the same chemical constitution, but different for molecules of different kinds.

We have now to consider how these molecules will pack themselves on passing from the fluid state, in which they can and do move about amongst themselves, into the solid state, in which they have no sensible freedom. If they attract one another, according to any law, and for my purpose gravity will suffice, then the laws of energy require that for stable equilibrium the potential energy of the system shall be a minimum. This is the same, in the case we are considering, as saying that the molecules shall be packed in such a way that the distances between their centres of mass shall on the whole be the least possible; or, that as many of them as possible shall be packed into unit space. In order to see how this packing will take place, it will be easiest to consider first the particular case in which the axes of the ellipsoids are all equal—that is, when the ellipsoids happen to be spheres. The problem is then reduced to finding how to pack the greatest number of equal spherical balls into a given space. It is easy to reduce this to the problem of finding how the spheres can be arranged so that each one shall be touched by as many others as possible. In this way the cornered spaces between the balls, the unoccupied room, is reduced to a minimum. You can stack balls so that each is touched by twelve others, but not by more. At first sight it seems as if this might be done in two ways.

In the first place we may start with a square of balls, as in Fig. 1, where each is touched by four others. We may then place another (shaded in the figure) so as to rest on four, and place four more in adjacent holes to touch it, as indicated by the dotted circles. Above these four more may be placed in the openings *a b c d*, so as to touch it—making twelve in all. If the pile be completed, we shall get a four-sided pyramid, of which each side is an equilateral triangle, as represented in Fig. 2. It will be seen that, in these triangular faces, each ball (except, of course, those forming the edges) is touched by six others.

---

[1] A Discourse delivered at the Royal Institution of Great Britain on Friday, May 15, 1891, by G. D. Liveing, F.R.S.

Again, if we start with such a triangle, as in Fig. 3, where each ball is touched by six others, we can place one ball —the shaded one—so as to rest on three others, and can then place six more round it and touching it, as indicated by the dotted circles. In three of the triangular holes between the shaded ball and the dotted balls touching it we can place three more, so as to touch the shaded ball—again twelve touching it in all. If we complete the pile, we shall get the triangular pyramid represented by Fig. 4, where each of the three sides is a right-angled triangle, while the base is an equilateral triangle. It will be seen that in the faces of this pyramid each ball (except those outside) is touched by four others. In fact, the arrangement in these faces is the same as in the base of the former pyramid; and the two arrangements are really identical in the interior, only one has to be turned over in order to bring it into parallelism with the other. Fig. 2 represents half a regular octahedron; Fig. 4 the corner of a cube. Ellipsoids, if they are all equal and similar to one another, can be packed in precisely the same way, so that each is touched by twelve others, provided their axes are kept parallel to each other —that is, if they are all oriented alike. This, then, by the laws of energy, will be the arrangement which the molecules will assume, in consequence of mutual attraction, in passing from a fluid to a solid state.

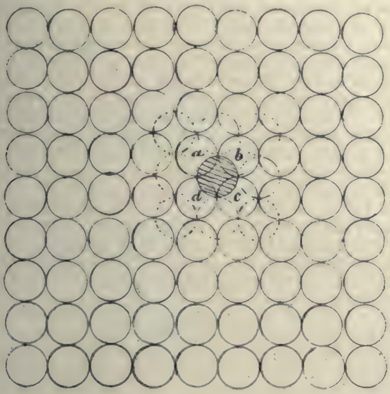

FIG. 1.

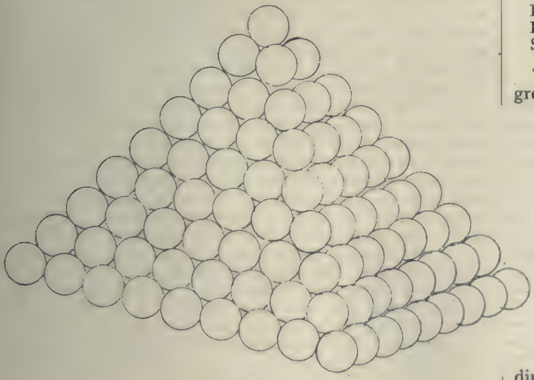

FIG. 2.

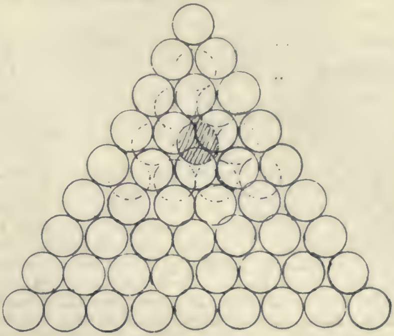

FIG. 3.

Next, let us see how the packing of the molecules will affect the external form. And here I bring in the surface-tension. We are familiar with the effects of this force in the case of liquids, and if we adopt the usually received theory of it, we must have a surface-tension at the boundary of a solid, as well as at the surface of a liquid. I know of no actual measures of the surface-tension of solids; but Quincke has given us the surface-tensions of a number of substances at temperatures near their points of solidification, in dynes per lineal centimetre, as follows :—

Platinum	1658	Antimony	244
Gold	983	Borax	212
Zinc	860	Sodium carbonate ...	206
Tin	587	Sodium chloride ...	114
Mercury	577	Water	86·2
Lead	448	Selenium	70·4
Silver	419	Sulphur	41·3
Bismuth	382	Phosphorus	41·1
Potassium	364	Wax	33·4
Sodium	253		

The surface-tensions of most of the solids are probably greater than these, for the surface-tension generally diminishes with increase of temperature; and you see that they amount to very considerable forces. We have to do, then, with an agency which we cannot neglect. In all these cases the tension measured is at a surface bounded by air, and is such as tends to contract the surface. We have, then, at the boundary between a crystallizing solid and the fluid, be it gas or liquid, out of which it is solidifying, a certain amount of potential energy; and by the laws of energy the condition of equilibrium is, that this potential energy shall be a minimum. The accepted theory of surface-tension is that it arises from the mutual

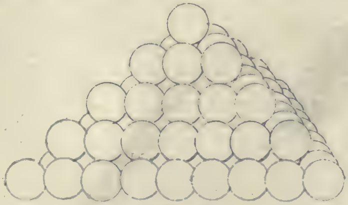

FIG. 4.

attraction of the molecules. The energy will therefore be a minimum for a surface in which the molecules are as closely set as possible.

Now, if you draw a surface through a heap of balls packed so that each is touched by twelve others, you will find that the surfaces which have the greatest number of centres of balls per unit area are all plane surfaces. That in which the concentration is greatest is the surface of a regular octahedron, next comes that of a cube, then that of a rhombic dodecahedron, and so on according to the law of indices of crystallographers.

The relative numerical values of these concentrations are as follows, taking that of the faces of the cube as unity:—

Octahedron	1·1547	Tetrakishexahedron	0·4472
Cube	1·0000	Eikositessarahedron	0·4083
Dodecahedron ...	0·7071	Triakisoctahedron ...	0·3333

We do not know that the surface-tension is exactly in the inverse proportion to the concentration, all that we can at present say is that it increases as the concentration diminishes.

If, then, the molecules occupy spherical spaces, the bounding surface will *tend* to be a regular octahedron.

But we have another point to consider. If a solid is bounded by plane surfaces, there must be edges where these planes meet. At such an edge the surface-tensions will have a resultant (see Fig. 5) tending to compress the mass, which must be met by a corresponding opposite pressure, and unless there is some internal strain there must be a corresponding resultant of the tensions on the opposite side of the crystal. Hence, if one face of a form is developed the opposite face will also be developed ; and generally, if one face of a form be developed all the faces will be developed ; and if one edge, or angle, be truncated, all the corresponding edges, or angles, will be truncated. Were it otherwise, there would not be a balance between the surface-tensions in the several faces. But there is another point to be taken into account. The surface energy may become less in two ways—either by reducing the tension per unit surface, or by reducing the total surface. When a liquid separates from another fluid, as chloroform from a solution of chloral hydrate on adding an alkali, or a cloud from moist air, the liquid assumes the form which, for a given mass, has the least surface—that is, the drops are spherical. If you cut off the projecting corners and plane away the projecting edges of a cube or an octahedron, you bring it nearer to a sphere, and if you suppose the volume to remain constant, you still diminish the surface. And if the diminution of the total surface is not compensated by the increased energy on the truncations, there will be a tendency for the crystals to grow with such truncations. The like will be true in more complicated combinations. There will be a tendency for such combinations to form, provided the surface energy of the new faces is not too great as compared with that of the first simple form.

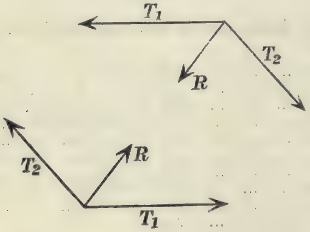

FIG. 5.

But it does not always happen that an octahedron of alum develops truncated angles. This leads to another point. To produce a surface in a continuous mass requires a supply of energy, and to generate a surface in the interior of any fluid is not easy. Air may be supersaturated with aqueous vapour, or a solution with a salt, and no cloud or crystals be formed, unless there is some discontinuity in the mass, specks of dust, or something of the kind. In like manner, if we have a surface already, as when a supersaturated solution meets the air or the sides of the vessel containing it, and if the energy of either of these surfaces is less than that of a crystal of the salt, some energy will have to be supplied in order to produce the new surface, but not so much as if there were no surface there to begin with. Hence, crystals usually form on the sides of the vessel or at the top of the liquid. When a solid separates from a solution there is generally some energy available from the change of state, which supplies the energy for the new surface. But at first when the mass deposited is very small the energy available will be correspondingly small, and since the mass varies as the cube of the diameter of the solid, whereas the surface varies as the square of the diameter, the first separated mass is liable to be squeezed into liquid again by its own surface-tension. This explains the usual phenomena of supersaturated solutions. A deposit occurs most easily on a surface of the same energy as that of the deposit, because the additional energy required is only for the increased extent of surface. It explains, too, the tendency of large crystals to grow more rapidly than small ones, because the ratio of the increase of surface to that of volume diminishes as the crystal grows.

While speaking of the difficulty of creating a new surface in the interior of a mass, the question of cleavage suggests itself. In dividing a crystal we create two new surfaces—one on each piece, and each with its own energy. The division must therefore take place most readily when that surface energy is a minimum. Hence the principal cleavage of a crystal made up of molecules having their motions comprised within spherical spaces will be octahedral. As a fact, we find that the greater part of substances which crystallize in the octahedral, or regular system, have octahedral cleavage. But not all ; there are some, like rock salt and galena, which cleave into cubes, and a very few, like blende, have their easiest cleavage dodecahedral. These I have to explain. I may, however, first observe that some substances—as, for instance, fluor-spar—which have a very distinct octahedral cleavage are rarely met with in the form of octahedra, but usually in cubes. In regard to this, we must remember that the surface energy depends upon the nature of both the substances in contact at the surface, as well as on their electrical condition, their temperature, and other circumstances. The closeness of the molecules in the surface of the solid determines the energy, so far as the solid alone is concerned ; but that is not the only, though it may be the most important factor conducing to the result. It is therefore quite possible that, under the circumstances in which the natural crystals of fluor were formed, the surface energy of the cubical faces was less than that of the octahedral, although when we experiment on them in the air it is the other way. This supposition is confirmed by the well-known fact that the form assumed by many salts in crystallizing is affected by the character of the solution. Thus alum, which from a solution in pure water always assumes the octahedral form, takes the cubic form when the solution has been neutralized with potash.

To return to the cubic and dodecahedral cleavages. If we suppose the excursions of the parts of the molecule to be greater in one direction than in the others, the figure within which the molecule is comprised will be a prolate spheroid ; if less, an oblate spheroid. Now, as already explained, the spheroids will be packed as closely as possible if the axes are all parallel and each is touched by twelve others. Now suppose the spheroids arranged as in Fig. 6, with their axes perpendicular to the plane of the figure; place the next layer in the black triangular spaces, and complete the pyramid. The three faces of the pyramid will be equal isosceles triangles; and if the spheroids be oblate, and the axis half the greatest diameter, the three angles at the apex of the pyramid will be right angles. The crystal will have cubic symmetry, but the relative condensation in the faces of the cube, octahedron, and dodecahedron, will be as 1 : 0·5774 : 0·7071. The easiest cleavage would therefore be cubic, as in rock salt and galena.

Again, if the spheroids have their axes and greatest diameters in the ratio of $1 : \sqrt{2}$, and we place four, as in Fig. 7, with their axes perpendicular to the plane of the figure, then place one upon them in the middle, and then four more upon it, in positions corresponding to those of the first four, we get a cubical arrangement, the centre of a spheroid in each angle of a cube, and one in the centre of the cube. Crystals so formed will have cubic symmetry, but the concentration of molecules will be greatest in the faces of the dodecahedron, and their easiest cleavage will be, like that of blende, dodecahedral.

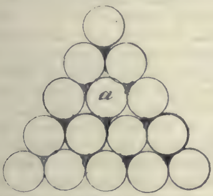

Fig. 6.

If spheroids of any other dimensions be arranged, as in Figs. 1 and 2, with their axes perpendicular to the plane of Fig. 1, we shall get a crystal with the symmetry of the pyramidal system. If the spheroids be prolate, the fundamental octahedron will be elongated in the direction of the axis, and if sufficiently elongated, the greatest condensation will be in planes perpendicular to the axis, and the easiest cleavage, as in prussiate of potash, in those planes. On the other hand, if the spheroids be sufficiently oblate, the easiest cleavage will be parallel to the axis.

If spheroids be arranged, as in Fig. 6, with their axes perpendicular to the plane of the figure, they will, in general, produce rhombohedral symmetry, with the rhombs acute or obtuse, according to the length or shortness of the axes of the spheroids. The cubical form already described is only a particular case of the rhombohedral. If the ratio between the axes of the spheroids and their greatest diameters be only a little greater, or a little less, than 1 : 2, the condensation will be greatest in the faces of the rhombohedron, and the easiest cleavage will be rhombohedral, as in calcite. If the spheroids be prolate, the easiest cleavage will be perpendicular to the axis of symmetry, as in beryl and many other crystals. Such crystals have a tendency to assume hexagonal forms—equiangular six-sided prisms and pyramids. To explain this, it may be seen in Fig. 6 that, in placing the next layer upon the spheroids represented in the figure, the three spheroids which touch that marked *a* may occupy either the three adjacent white triangles or the three black ones. Either position is equally probable. The layer occupying the white triangles is in the position of a twin to that occupying the black triangles. So far as the central parts of the layer are concerned, it will make no difference in which of these ways the molecules are packed. It is only at the edges that the surface-tension will be affected. If the form growing be a rhombohedron, a succession of alternating twins will produce a series of alternating ridges and furrows in the rhombohedral faces, which will give rise to increased surface-tension, which will tend to prevent the twinning. On the other hand, an hexagonal form and its twin, formed in the way indicated, are identical, and we have in this fact a cause tending to the production of hexagonal forms. This tendency is increased by the fact that, for a given volume, the total surface of the hexagonal forms is in general less than that of the rhombohedral. Indeed, such forms lend themselves to the formation of almost globular crystals, as is well seen in pyromorphite and mimetite.

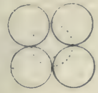

Fig. 7.

If the spheroids be arranged with their axes in other positions than those we have been discussing, or if the molecules occupy ellipsoidal spaces, they will, when packed so that each is touched by twelve others, give figures of less symmetry. The results may be worked out on the lines indicated in the foregoing discussion, and will be found to correspond throughout to the observed facts.

Bravais long ago proposed various arrangements of molecules to account for crystalline forms, and Sohncke has extended them to further degrees of complication in order to account for additional facts in crystallography. But neither of them has given any reason why the molecules should assume such arrangements. To me it seems that only one arrangement can be spontaneously assumed by the molecules, and that the varieties of crystalline form depend on the dimensions of the ellipsoids and the orientation of their axes. Curie also has indicated that the development of combined forms, as those of cube and octahedron, will depend on the surface-tensions in the faces of these forms, but he has not indicated how the surface-tension is connected with the crystalline arrangement, or why the energy of a cubic face should be greater or less than that of an octahedral face.

We are now in a position to understand the interesting facts brought forward by Prof. Judd in a discourse delivered at the Royal Institution early this year. However long a crystal has been out of the solution, or vapour, from which it was formed, its surface-tension will remain unaltered, and when it is replaced it will grow exactly as if it had not been removed. Also, if any part be broken off it, the tension of the broken surface will, if it be not a cleavage face, be greater than on a face of the crystal, and in growing, the laws of energy necessarily cause it to grow in such a way as to reduce the potential energy—that is, to replace the broken surface by the regular planes of less surface energy. The formation of "negative crystals" by fusing a portion in the interior of a crystalline mass, is due to the same principle. Surfaces of least energy will be most easily produced inside as well as outside, and in a crystalline mass of course they will be parallel to the external faces of the crystal. We see the same thing in the action of solvents. Most metals assume a crystalline texture on cooling from fusion, and when slowly acted on by dilute acids the surfaces of greater energy are most easily attacked, in accordance with the laws of energy, and the undissolved metal is left with surfaces of least energy which are the faces of crystals. This is easily seen on treating a piece of tin plate, or of galvanized iron, with very dilute aqua regia. In fact, solution is closely connected with surface energy. It is probably the low surface energy of one form of crystals of sulphur which makes them insoluble in carbon disulphide, and this low surface energy may be an electrical effect.

I pointed out that the development of all the faces of a form, and the similar modification of all corresponding edges and angles of a crystal, is in general necessary in order to produce equilibrium under the surface-tensions. But we sometimes find crystals with only half the modifications required for symmetry. In such cases the surface-tensions must produce a stress in the interior tending to deform the molecules. When the crystal was growing, there must have been equilibrium, and therefore a pressure equal and opposite to this effect of the surface-tension. There are various ways in which we may suppose that such a force would arise. The electric field might give rise to a stress in opposition to the aggregation of the molecules in the closest possible way, and then the crystal would grow such faces as would produce an equal and opposite stress. Inequalities of temperature, or the presence of molecules of other kinds amongst those of the crystal, might produce similar results. When the stress due to electricity, or to temperature, was removed by change of circumstances, that due to the surface-tensions would persist, and the crystal would be left with an internal strain. Crystals of this sort, with unsymmetric faces, generally betray the internal strain, either by developing electricity of opposite kinds at the two ends when heated or cooled, or they affect polarized light, rotating the plane of polarization. That these effects are due to the internal strain is shown by the fact that tourmalines, and other crystals, which are pyro-electric when unsymmetrical, show no such property when symmetrically grown. Also sodium chlorate in solution, quartz when fused, and so on, lose their rotatory power. Substances which in solution show rotatory power, as a rule develop unsymmetric crystals. This is well seen in the tartrates. The constitution of the molecules must be such that they will not, without some strain, form crystals; and equilibrium, when the crystal is growing, is attained by means of the opposing stress due to want of symmetry in the surface-tensions. In all such crystals the rotatory power of the solution disappears in whole or in part. We cannot test this in biaxial crystals, but, according to Des Cloiseaux, sulphate of strychnine is the only substance which shows rotation both in the solution and in the crystalline form, and in it the rotatory power is much increased by the crystallization. Effects comparable with these may be produced by mechanical means. A cube of rock salt, which has no effect on plane-polarized light in its ordinary state, changes the plane of polarization when it is compressed in a vice. And a cleavage slice of prussiate of potash, which is uniaxial, may by compression be distorted so as to give in a convergent beam of polarized light elliptical rings, and two eyes like a biaxial crystal.

THE ERUPTION OF VESUVIUS OF JUNE 7, 1891.

DURING the latter part of 1890 and the early part of the present year, the central activity of Vesuvius has very slightly varied, except about the new year, when it was considerably increased, rising to the third or fourth degree, simultaneous with the stoppage of the lateral outflow of lava that had been going on since August 7, 1890. Since then, up to the present outburst, the central activity has been generally at the first degree, and the cone of eruption has slowly grown in height.

On June 1 there was a crater within the central eruptive cone, of about 50 m. in diameter, near the centre of which was the eruptive vent, surrounded by another embryonic eruptive cone. On that day, four small eruptive mouths opened around the embryonic cone in the bottom of the central crater, the smallest being to the east.

Thus the volcano remained till June 7, at 10 a.m., when activity stopped, only a small quantity of vapour escaping from central vents. At midday a radial cleft opened at the north toe of the cone of eruption (May 1889, June 1891) traversing towards its east end, the little sickle-shaped ridge, the remnant of the 1885–86 crater, but, as yet, gave out little vapour. At 4 to 4.30 p.m., shocks of earthquake commenced, limited only to the upper slopes of Vesuvius, and simultaneous with the extension of the radial fissure down the side of the great Vesuvian cone for nearly half its way opposite the Punta del Nasone of Monte Somma, from which, at about 5.30 p.m., issued a little lava, whilst from the upper extremity of the fissure at the toe of the cone of eruption much vapour escaped, so that from Naples the smoke-plume arose from this point. From 5.30 to 7 p.m. the fissure still extended lower, accompanied from time to time by local earthquakes, noises, and the elevation of columns of black dusty smoke. At a few minutes to 7 the floor of the Atrio del Cavallo was reached, and a remarkably black column of smoke had arisen.

My friend Dr. L. Sambon saw this column arise, and came to inform me immediately, as I had left off watching the mountain at 5.30. After taking a photo of the mountain, we left Naples at 9 p.m., spent some time in inquiries at Resina and near the Observatory. Everything was now dark, as the volcano had calmed down at 8 p.m. At 2 a.m., June 8, we were at the eastern extremity of the Observatory ridge, and commenced to wend our way across the lava surface towards Monte Somma. We were at the lowest part of the depression at the west end of the Atrio del Cavallo, where it joins the Fossa della Vetrana, and along which some of the largest lava-streams have flowed (1855, 1872, &c.), when suddenly on our right above us (2.23 a.m.) a vast quantity of bright red vapour arose from the new outpour of lava. We hastened our steps as much as the road and our lantern would allow us, so as to reach the escarpment of Monte Somma, the foot of which was followed till near the Punta del Nasone, and close to the theatre of eruption. Here we clambered up some distance above the level of the Atrio to watch events whilst we ate our late supper or early breakfast. Along the slope of the great cone in the line of fissure were a few luminous points from some pieces of still uncooled lava of the little that had oozed forth from the lower half of the fissure. At about 60 or 80 yards from the foot of the great cone two or three fountains of lava were throwing up jets of molten rock for 2 or 3 m., and the lava was slowly spreading out on the almost horizontal plain of the Atrio in several tongues. The lava must have still been high in the main chimney, as the vapour that issued at the top of the fissure showed a slightly red illumination. So we remained till daylight, when we could see the fissure on the side of the cone. The mouth that formed at 5.30 the previous day was still smoking a little, whilst the fissure below it sent off several ramifications at an acute angle like the branches of an inverted tree, from several of which little streams of lava had been given out, where they had soon consolidated. We now followed the base of the great cone to the lower railway station, where we found all the people up and dressed, frightened by the strong shock and noises at 2.23 a.m., coincident with the fresh outflow of lava that we had witnessed, but which shocks we had not felt, although they were described as the strongest that had been felt.

Having ascended to the summit of Vesuvius, we found the central crater rapidly enlarging by the falling in of its edges. From the new fissure at its summit was issuing much vapour under pressure, and rich in sulphurous acid, which is, even in traces, intolerable; and the hot air coming from innumerable new fissures rendered approach very difficult. We did, in fact, once jump across part of the fissure, but returned much quicker on account of the hot irritant vapours. An approach from the opposite side was equally unsuccessful. At some old fumaroles on the 1872 crater plain, I collected some crusts of boric acid and alum, both rare products at this volcano.

One of three terminations we may expect to these phenomena, which are very characteristic of a lateral disruption, so common at Vesuvius:—

(1) Should the lava cool sufficiently to plug the radial dyke, no further phenomena will occur, and activity will be restored to the central vent.

(2) If this plugging only partially takes place, lava may dribble forth for months, but probably the escape of vapour will soon be restored to the central vent.

(3) If the rent should widen, considering how low it extends, we may expect a grand eruption which might rival that of 1872, which commenced near the same spot and much in the same way; the mechanism by which this occurs I have explained elsewhere.[1]

My best thanks are due to Mr. L. Sambon for his company and help, and to Mr. E. Treiber, Inspecting Engineer of the Vesuvian Railway, for kind information.

Naples, June 9. H. J. JOHNSTON-LAVIS.

NOTES.

A LARGE and influential meeting was held at Edinburgh on Monday to consider the arrangements which ought to be made for the visit of the British Association to that city next year. The Lord Provost presided. On the motion of Sir William Turner the following were elected Vice-Presidents:—The Lord Provost, the Marquis of Lothian, the Earl of Rosebery, Lord Kingsburgh, Principal Sir William Muir, and Prof. Sir Douglas Maclagan. A local executive committee was chosen, and Mr. A. Gillies Smith was appointed honorary local treasurer. In a letter from Mr. Griffiths, secretary of the Association, it was stated that Sir Archibald Geikie, who will preside over the Edinburgh meeting, was in favour of the meeting being held early in August. A considerable majority, however, voted in support of a proposal that the meeting should begin on Wednesday, September 28.

ON July 28 and the three following days, at Bournemouth, the British Medical Association will hold its fifty-ninth annual meeting under the presidency of Dr. J. Roberts Thomson. The scientific business of the meeting will be conducted in nine sections. An address in medicine will be given by Dr. Lauder Brunton; an address in surgery by Prof. Chiene; and an address in public medicine by Dr. Cox Seaton.

A PHYSICAL Observatory, furnished with specially designed apparatus for the prosecution of investigations in radiant energy and other departments of telluric and astro-physics, has been established as a department of the Smithsonian Institution. The communication of new memoirs bearing in any way on such researches is requested, and for them it is hoped that proper return can be made in due time.

THE *Standard* understands that on the vote for the salary of the President of the Board of Trade, either Sir Henry Roscoe or Sir Lyon Playfair will call attention to the action of the Government with regard to the proposed Institute of Preventive Medicine.

THE Committee of the French Academy has decided, by five votes to four, that the prize of 20,000 francs should be given to M. Elisée Reclus, author of the well-known "Nouvelle Géographie Universelle." It is expected that the Academy will ratify the decision.

ACCORDING to a Reuter's telegram from Simla, dated June 12, Drs. Rake and Buckmaster have succeeded in cultivating the leprosy bacillus in serum. They were aided in their researches by Surgeon-Major Thomson.

IN reply to Mr. Bryce, in the House of Commons on Monday, the Lord Advocate stated that it would be the duty of the Government during the ensuing year not only to weigh very carefully the claims of secondary education in Scotland as one of the interests competing for a share of the additional Scotch grant, but also to prosecute further inquiries as to the means by which any grant available for that purpose might be usefully applied. Many proposals had already been submitted to and considered by the Scotch Education Department, and these, as well as any suggestions which might be made, would receive further careful consideration. The Government would also endeavour to bring all necessary statistics down to the latest date, so as to afford the necessary information for the solution of all branches of this difficult question.

THE funeral of Sir Richard Burton took place on Monday at the church of St. Mary Magdalene, Mortlake. The tomb represents an Arab tent, with a crucifix over the entrance. The interior is a small chapel with altar and some Oriental lights.

IT has been decided that a Geographical Society shall be formed at Liverpool. A preliminary committee has been appointed, and it has issued a circular stating the objects of the new body.

ACCORDING to a telegram sent through Reuter's Agency from Naples on June 16, the flow of the lava stream from Vesuvius had stopped, and Signor Palmieri, the Director of the Observatory on the mountain, had expressed his belief that the outflow might be regarded as at an end.

SLIGHT but continuous earthquake shocks were felt at Verona on June 10; and on the 11th, at 8.30 a.m., a very violent shock occurred at Tregnano and Badia Calavena. This was plainly felt in Verona also. Another violent shock occurred at Tregnano on the 13th, and on the 15th shocks were reported from Castelnuovo, Peschiera, Somma Campagna, and Desenzano.

THE first volume of a new meteorological Review has been published, containing observations taken in the south-west of Russia for the year 1890. This system was organized by Prof. A. Klossovsky in 1886, and now numbers nearly 600 observers. The observations refer chiefly to temperature, wind, rainfall, &c., for climatological and agricultural purposes. The Review also contains several articles of importance, *e.g.* (1) on phenological phenomena; (2) on the harvests in connection with meteorological observations; (3) on the movements of clouds; (4) actinometric observations made at Kieff. These are written in the Russian language only; the positions of the stations, and various data referred to in the text, are illustrated by maps and diagrams.

AT a meeting of the Royal Statistical Society, on Tuesday, a paper was read by Mr. Noel A. Humphreys, Secretary of the Census Office, on the results of the recent census and estimates of population in the largest English towns. The first part of the paper was devoted to the consideration of the recently-issued results of the census in April last in the twenty-eight large English towns dealt with in the Registrar-General's weekly returns. It was pointed out that, although the increase of population within the present boundaries of these towns showed an increase of nearly a million in the last ten years, the increase was less, by considerably more than half a million (605,318), than would have been the case if the rate of increase had been the same as in the preceding ten years, 1871–81; and that the rate of movement of population showed striking variations in the different towns. The rate of increase in these twenty-eight towns, it was stated, has pretty constantly declined in recent years, and has fallen with scarcely a break during the last five intercensal periods from 24·3 per cent. in 1841-51 to 11·0 per cent. in 1881-91. The percentage of increase within the boundaries of registration London (practically those of the county of London) declined in the same period from 21·2 to 10·4. The rate of actual decline of population in central London continues to increase, and the rate of increase of the other parts of the metropolis, including even the aggregate outer ring of suburban districts, continues to decline. Examined in detail, the provincial towns show, with few exceptions, the operation of similar laws; actual decrease in the central portions, and marked decline in the rate of increase in the other portions, the latter being specially noticeable in those towns with comparatively restricted areas. This examination, while showing the marked general decline in the rates of increase in these towns, discloses striking variations in the rates of increase in successive census periods. Mr. Humphreys called attention to the fact that these striking changes in the rates of movement of population in the large towns interpose the greatest difficulty in estimating, even approximately, their population in intercensal periods. The estimate of population in Liverpool, based upon the rate of increase between 1871 and 1881, exceeded the recently enumerated number by more than 100,000, or by 20 per cent.; while in Salford the percentage of over-estimate, by the same method, was 26 per cent. Thus the recent birth-rates and death-rates in these two towns have been under-estimated by no less than a fifth and a fourth, respectively. The various methods that have been at different times suggested for estimating the population of towns in intercensal years, in substitution of Dr. Farr's method, still used by the Registrar-General's Department, were severally considered, and it was shown that no hypothetical method yet devised affords reasonable promise of satisfactory results. It was therefore urged that a quinquennial census could alone supply a remedy for the present difficulty, which threatens to impair the public faith in death-rates, the failure of which would most seriously hinder and imperil the health progress of the country.

At the meeting of the Linnean Society of New South Wales, on April 29, Mr. T. W. Edgeworth David exhibited, on behalf of Mr. J. E. Carne, Mineralogist to the Department of Mines, Sydney, a specimen of precious opal from the White Cliffs about fifty miles northerly from Wilcannia. Precious opal and common opal have lately been discovered in this locality in a formation corresponding to the Desert Sandstone of Queensland. The opal occurs disseminated as an infiltrated cement throughout the mass of the sandstone in places, and also replacing the calcareous material of fossils. It also occurs in cracks in the sandstone and in fossil wood, which is somewhat plentifully distributed throughout the sandstone, and occasionally replaces part of the original woody tissues of the silicified trees.

Mrs. J. King van Rensselaer contributes to the Proceedings of the U.S. National Museum an interesting paper on the playing cards used in Japan. They are more distinctly original, she says, than any others, and show no marks of the common origin which the Italian, Spanish, German, French, Hindoo, and Chinese cards display. Forty-nine in number, they are divided into twelve suits of four cards in each suit. One card is a trifle smaller than the rest of the pack, and has a plain white face not embellished with any distinctive emblem, and this one is used as a "joker." The other cards are covered with designs that represent the twelve flowers or other things appropriate to the weeks of the year. Each card is distinct and different from its fellows, even if bearing the same emblem, and they can be easily distinguished and classified, not only by the symbolic flowers they bear, but also by a character or letter that marks nearly every card, and which seems to denote the vegetable that represents the months. The only month that has no floral emblem is August, and that suit is marked by mountains and warm-looking skies.

Prof. D'Arcy W. Thompson has edited an interesting volume of "Studies from the Museum of Zoology in University College, Dundee." The volume consists of the first twelve numbers of a journal in which the zoologists connected with the Dundee University College hope to find "an incentive to their own diligence, a way of communication with the outer world, and a means of giving direction and consecutive purpose to all their work." The editor contributes five papers, and the writers associated with him are Miss Mary L. Walker, Prof. H. Leboucq, Dr. H. St. John Brooks, Mr. Alexander Meek, and Prof. W. K. Parker.

An interesting illustration of the antagonistic action of poisons is mentioned in the current number of the *Pharmaceutical Journal*. Dr. Mueller, of Yackandandah, Victoria, has written a letter in which he states, says our contemporary, that in cases of snake bite he is using a solution of nitrate of strychnine in 240 parts of water mixed with a little glycerine. Twenty minims of this solution are injected in the usual manner of a hypodermic injection, and the frequency of repetition depends upon the symptoms being more or less threatening, say from 10 to 20 minutes. When all symptoms have disappeared, the first independent action of the strychnine is shown by slight muscular spasms, and then the injections must be discontinued unless after a time the snake poison reasserts itself. The quantity of strychnine required in some cases has amounted to a grain or more within a few hours. Both poisons are thoroughly antagonistic, and no hesitation need be felt in pushing the use of the drug to quantities that would be fatal in the absence of snake poison. Out of about 100 cases treated by this method, some of them at the point of death, there has been but one failure, and that arose from the injections being discontinued after 1¼ grain of strychnine had been injected. Any part of the body will do for the injections, but Dr. Mueller is in the habit of making them in the neighbourhood of the bitten part or directly upon it.

The Rev. J. Hoskyns-Abrahall writes to us that on June 10, about 10.30 p.m., near Woodstock, he saw what he describes as "a beautiful phenomenon." "Suddenly," he says, "at the zenith, east of the Great Bear, shone forth a yellow globe, like Venus at her brightest. Dropping somewhat slowly, it fell obliquely southward. As it passed in its brilliant career, it lighted up its dusky path with a glorious lustre. When it had descended about half-way down toward the horizon, it burst into a sparkling host of glowing fragments, each dazzlingly shot over with all the hues of the rainbow."

The Register of the Johns Hopkins University for 1890–91 has been issued. It contains a great mass of well-arranged facts relating to the work of that flourishing institution.

Mr. C. French, Government Entomologist at Melbourne, is contributing to the *Victoria Naturalist* a series of notes on the insectivorous birds of Victoria. In the first paper, which appears in the May number, he describes the Australian Bustard (*Choriotis australis*). Some months ago Mr. French made an appeal to the Victorian Government for the permanent protection of this, the most useful insect-destroying bird in the colony. His appeal was supported by the Council of the Zoological Society of Melbourne; and the Government has not only acceded to the request, but has placed the matter before the Government of New South Wales, who, it is hoped, will at once see the necessity for the preservation of so valuable a bird.

Dr. A. Koenig has issued as a separate volume the account of his ornithological observations made during his explorations in Madeira and the Canary Islands. It is a notable memoir, and several new species and sub-species of birds are described. He is somewhat severe on some British ornithologists for having tried to forestall him in the description of the Chaffinch of Palma, which he was the first to discover. The editor of the *Journal für Ornithologie*, in which the paper first appeared, also adds some strictures on the ways of British naturalists. Dr. Koenig apparently has some grounds for his complaint, but a *tu quoque* argument could be upheld against him, for he persists in calling a *Regulus* by his new name of *satelles*, though he admits that it is *Regulus teneriffæ* of Seebohm, and he does not refer to the British Museum "Catalogue of Birds," in which he will find that his identifications of the Madeiran and Canarian *Fringillæ* were all published long before he gave them to the world as new facts. These small matters do not, however, affect the importance of the essay, which is worked out with remarkable care, and is, in fact, a monographic review of the ornithology of Madeira, Teneriffe, and Palma. Eight coloured plates illustrate the article.

In a paper lately read before the Scientific Section of the Manchester Literary and Philosophical Society, Mr. John Watson maintains that the re-development of lost limbs is not unusual among insects. He himself has had three cases in which limbs have been re-developed, and one case of complete cicatrization. Re-development, he says, can take place either at the larval or the pupal stages of an insect's metamorphosis.

The British Consul at Hankow, writing of the varnish exported from that city, says he is informed that it is the gum of a tree—the *Rhus vernicifera*. On this tree, before daylight, incisions are made; the gum that runs out is collected in the dark, and strained through a cotton cloth bag, leaving behind a large amount of dirt and refuse. This operation can only be performed in the dark, as light spoils the gum and causes it to cake with all the dirt in it. It cannot be strained in wet weather, as moisture causes it to solidify. When the Chinese use this varnish, they rub it on with a sort of mop, or swab, made of soft waste silk. It should only be used in wet weather, as, if the atmosphere is dry when it is rubbed on, it will always be sticky. As used by the Chinese, the varnish takes about a month to dry, and during the time it is drying it is poisonous to the eyes. The Consul thinks that this gum may have been one of the ingredients of the celebrated Cremona varnish, and he suggests that it might be worth the while of musical instrument makers to make experiments with it with a view to producing a varnish that would give a mellow instead of a glassy sound.

The Insect-house in the Zoological Society's Gardens is now in excellent order, and well deserves a visit. In addition to the Silk-moths that are usually present during the warm weather, the Papilioninæ, or Swallow-tail butterflies, afford at the present time the chief display. The perfect insects of several species of the genus *Papilio* have appeared—*P. cresphontes*, *ajax*, and *asterias* from North America, *P. alexanor* from the Mediterranean shores, and the handsome *P. maackii* from Japan. The last-named has been seen for the first time in the house this year, and offers a striking contrast to the other species of the genus that have previously been exhibited in the Gardens, it being of black and golden-green colours instead of the yellows and blacks that we are accustomed to in our European Swallow-tails. *P. cresphontes* has appeared in large numbers in the house, but no varieties have been obtained. This also is the first season for two other beautiful Papilioninæ, viz. *Doritis apollina* from Asia Minor, and the Japanese *Sericina telamon.* The latter shows considerable difference in the markings of the sexes. The North American *Limenitis disippus* can be at present seen in all its stages, and is well worthy of attention, the caterpillar moving along the leaf-stalks with a peculiar interrupted gait. Of the Sphinx moths, the South European *Deilephila alecto* has already appeared, and *D. nicæ* is expected. These insects are, however, not seen to advantage in confinement, as their superb powers of flight cannot be displayed in a small compartment. Two examples of the Orthoptera are alive in the house—*Diaphemora femorata*, one of the Stick- or Twig-insects from North America, and *Empusa egena* from Southern Europe. The former has been reared from eggs laid in the Insect-house, but these progeny are not so healthy as those obtained from freshly-imported eggs. The *Empusa* is of a most bizarre form, and belongs to the family Mantidæ, the species of which feed only on living creatures. The public is indebted to Mr. S. H. Carver for the opportunity of seeing living scorpions; he has sent examples of two species of this group from Egypt, both of which unfortunately are unidentified, there being obvious difficulties in the way of carrying about live scorpions and comparing them with dried specimens. There is a third scorpion, from South Europe, living with its Egyptian congeners; it has a small delicate tail, and is altogether a less frightful creature, though assuming a menacing attitude with equal readiness. A spider, *Lycosa portosantana*, from Madeira, is healthy, and is a fine creature, though insignificant by the side of its neighbour, a huge *Mygale* from South America. The latter, as well as the scorpions, is fed with mice, which are given to it dead, though in its native haunts a *Mygale* has been known to prey on living individuals of these small mammals.

In the current number of the *Board of Trade Journal* some interesting facts as to cotton cultivation in Russian Turkestan are given, on the authority of a Russian correspondent of the *Monde Économique*. After the submission of the Khanates of Central Asia, the trade of the country was carried on chiefly with the towns of Russia in Europe, and was confined at first to the export in small quantities of cotton grown from native seeds, of rice, raw silk, and other similar products. It is only during the last ten years that the industry of the country has extended to any considerable degree, owing to the ingress of speculators, and has changed its primitive character. There have been established all kinds of works and factories, and in 1884 the cultivation of cotton of American origin was essayed. This trial succeeded so well that all classes of society, including even public officials, devoted themselves to this culture, which has become one of the chief branches of industry in the country. The new cotton produced in Central Asia is equal to that of America, and finds an excellent outlet among the cotton spinneries and mills of Russia. But the consumption in European Russia does not suffice for the ambitious aims of native producers, and they look forward to the possibility of opening up trade in the foreign markets of Europe.

The new number of the *Internationales Archiv für Ethnographie* fully maintains the reputation of this excellent periodical. Among the contents is a paper in which Dr. J. D. E. Schmeltz continues his elaborate account of the collections from Corea in the ethnographical museum at Leyden. Dr. Heinrich Schurtz has an interesting article on the geographical distribution of negro costume. As usual, the plates illustrating the various contributions are most carefully executed.

A further communication upon the new peroxide of sulphur, SO_4, by Prof. Traube, of Breslau, will be found in the current number of the *Berichte.* This interesting substance is obtained when solutions of sulphuric acid containing at least 40 per cent. of acid are subjected to electrolysis, as a crystalline deposit upon the anode. The crystals were first observed some time ago by Berthelot, but were considered by him as identical with the oxide S_2O_7, which he had previously obtained by the action of the silent electrical discharge upon a mixture of sulphur dioxide and oxygen. Prof. Traube, however, finds that the substance obtained at the anode in the electrolysis of 40 per cent. solutions of sulphuric acid is represented by the formula SO_4, and is quite a different substance from Berthelot's S_2O_7. It is, as predicted by

Mendeleeff, not the anhydride of an acid, but a neutral oxide of a similar chemical character to hydrogen peroxide. It may be best separated from the excess of 40 per cent. acid by removing the latter, after dilution with three times its volume of water, by means of freshly prepared barium phosphate. It cannot, however, be preserved in pure water, as it parts with oxygen so readily, becoming reduced thereby to ordinary sulphuric acid. That it is not an anhydride is proved by the fact that it yields no salts of the type K_2SO_5 with alkalies. Neutral solutions containing it, in which it appears to be permanent, may be readily prepared by neutralizing the solution in 40 per cent. acid with caustic soda, potash, or magnesia. The properties of SO_4 in either acid or neutral solution are somewhat remarkable. When boiled in contact with platinum wire or platinum black it is energetically decomposed with evolution of quantities of oxygen. If the neutral solution is employed, it becomes strongly acid. Indigo solution is oxidized and decolorized slowly, but instantly if a little ferrous sulphate is added. SO_4, however, in spite of this ready decomposition into oxygen and sulphuric anhydride, is but a weak oxidizing agent, being incapable even of oxidizing oxalic acid or carbon monoxide. But under certain circumstances it acts as a powerful reducing agent. For instance, if an emulsion of peroxide of lead in 40 per cent. sulphuric acid is brought in contact with a quantity of similar acid which has been subjected to electrolysis so as to charge it with SO_4, a rapid evolution of oxygen gas occurs, and the peroxide of lead is converted into ordinary sulphate of lead. In a similar manner precipitated peroxide of manganese is rapidly reduced to manganous sulphate with evolution of oxygen, and silver peroxide likewise dissolves up to a clear solution of silver sulphate with violent effervescence due to the escape of oxygen. Prof. Traube regards sulphur peroxide as built up on the type $SO_2(O_2)$, resembling hydrogen peroxide, H_2O_2. He considers that Berthelot's oxide, S_2O_7, is a molecular compound of SO_3 and SO_4, for it does not dissolve in water without decomposition, breaking up into sulphuric anhydride and oxygen, which is evolved. On the other hand, it appears, like SO_4, to be perfectly stable in a moderately concentrated solution of sulphuric acid.

The additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus* ♂) from India, presented by Mr. James B. Leckie; a White-fronted Amazon (*Chrysotis leucocephala*) from Cuba, presented by Mrs. Lacabra; a Radiated Tortoise (*Testudo radiata*) from Madagascar, an Angulated Tortoise (*Chersina angulata*), three Smooth-bellied Snakes (*Homolosoma lutrix*) from South Africa, presented by the Rev. G. H. R. Fisk, C.M.Z.S.; a Green Lizard (*Lacerta viridis*) from France, presented by Mrs. Hill; three Horned Lizards (*Phrynosoma cornutum*) from Texas, presented by Mr. James E. Talmage; five Squirrel-like Phalangers (*Belideus sciureus* ♂ ♂ ♂ ♀ ♀) from Australia, a Grand Eclectus (*Eclectus roratus*) from Moluccas, deposited; two Elliot's Pheasants (*Phasianus ellioti* ♀ ♀) from China, two Rufous Tinamous (*Rhynchotis rufescens*) from Brazil, purchased; two Marbled Newts (*Molge marmorata*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

Newly-discovered Markings on Saturn.—*Edinburgh Circular* No. 16, issued by Dr. Copeland on June 10, contains the following information:—

Mr. A. Stanley Williams, of Burgess Hill, Sussex, has discovered three delicate but distinct markings in the equatorial region of Saturn. The first and third of these are round bright spots, somewhat brighter than the white equatorial zone in which they occur. The second is a smaller dark marking on the equatorial edge of the shaded belt which forms the southern boundary of the white zone. Mr. Williams has obtained abundant proof of the reality of these markings, but points out that it requires patience and practice to see them readily. It is very desirable to obtain repeated observations of their times of transit across the planet's central meridian. To facilitate these observations, Mr. Williams has prepared the following table, using 10h. 14·6m. as the provisional time in which the planet rotates on its axis:—

Approximate Greenwich Mean Time at which the Spots may be expected on Saturn's Central Meridian.

1891.	Spot 1 (white).		Spot 2 (dark).		Spot 3 (white).

The Rotation Period of Venus.—The *Bulletin de l'Académie Royale de Belgique*, No. 4, contains a paper, by M. Niesten, of Brussels Observatory, *à propos* the rotation of the planet Venus. The observations and drawings made by M. Stuyvaert and the author from 1881 to 1890 do not appear to confirm the persistence of the dark markings during a long period, as found by Schiaparelli and others. It is also shown that De Vico's period of 23h. 21m. 21·93s. is more in accordance with the observations than Schiaparelli's period of 224·7 days. Twelve drawings of the planet, and a map showing all the markings, accompany the paper.

A New Asteroid (310).—M. Charlois discovered the 310th minor planet on May 16. Its magnitude was 13.

THE ROYAL GEOGRAPHICAL SOCIETY.

The anniversary meeting of the Royal Geographical Society was held in the University of London on Monday afternoon, the President, Sir Mountstuart Grant-Duff, in the chair. The first business was the award of the medals and other honours for the year. The Founder's Medal was delivered to Sir Dillon Bell, Agent-General for New Zealand, for transmission to Sir James Hector, K.C.M.G., F.R.S., Director of the New Zealand Geological Survey. The Swedish Minister received the Patron's Medal on behalf of Dr. Fridtjof Nansen, who was unable to attend. Other honours were awarded to Mr. William Ogilvie, for his explorations of the Mackenzie and Yukon regions; Lieutenant B. L. Sclater, for instruments to be used in the exploration of Nyassaland; Mr. A. E. Pratt, for his journeys in Szechuen; Mr. W. J. Steains, for his investigations on the Rio Doce, South America. Mr. H. J. Mackinder then introduced the students of the Training Colleges who had been successful in obtaining the prizes offered by the Society annually on the results of the Christmas examinations in geography. Mr. Mackinder spoke briefly on the progress of geographical education, and on the results of the four years' awards to the Training Colleges.

The Secretary then read the annual report of the Society, from which it appears that on May 1 last the total number of Fellows was 3579, being a net increase of 84 on the previous year. The total income up to the end of December 1890 was £9531, and expenditure £8218. The estimated value of the Society's investments is £25,648, and of its total assets £46,248. During the past year, 900 books and pamphlets have been added to the library, and 936 sheets of maps to the map collection, besides 25 atlases, 700 photographs, 151 lantern-slides, and 51 views.

The President then proceeded to deliver the annual address on the progress of geography during the past year, dealing mainly with the explorations which have been carried on in various parts of the world.

"The year," he said, "of which I am about, with your permission, to give some account, has not been, so far as geographical discoveries are concerned, a very brilliant or sensational one. Brilliant and sensational years are, alas! likely to grow fewer and fewer as the globe we inhabit becomes ever better known to us. If, however, the year has not been made memorable by much *extensive* exploration it has put to its credit no small amount of *intensive* exploration. A good many gaps in our knowledge have been filled up, and a great deal of solid useful work accomplished. All this healthy activity has been represented in our Proceedings, and much of it has found its way to our Fellows through the papers which have been read in this theatre. Many of these have been extremely interesting. I may mention particularly the account of Messrs. Jackson and Gedge's journey to Uganda, Colonel Tanner's observations on the Himalayan Range, and Mr. Pratt's journey to Szechuen. These last were illustrated, as it will be remembered, by drawings and by photographs of exceptional merit, which were examined carefully by large numbers after our meetings closed. As you will have learnt from the report of the auditors, the total assets of the Society have considerably increased, and we are in a position to give most efficient assistance to any thoroughly well considered schemes which are laid before us. I am very sure, however, that the Fellows will consider that, although we are rich, it is none the less our duty to scrutinize carefully all proposals which are made to us, and to see that the money which they give so generously is applied only to really promising objects. Such we considered to be Mr. Ramsay's explorations in Asia Minor, and Mr. Theodore Bent's examination of the remarkable ruins at Zimbabye in South Africa. Instruments to the value of over £600 have been lent during the past year to intending travellers, and thirty-six gentlemen have received instruction from Mr. Coles, partly at the expense of the Society, for the purpose of making them more efficient as explorers. Our duties dividing themselves into two great classes—the acquisition of knowledge and the diffusion of knowledge—I think the Society will hail with pleasure a considerable increase of our expenditure under the head of 'Scientific Purposes,' which amounted for last year to nearly £600. That sum included £178 for the purpose just alluded to, £120 for the promotion of geographical education in connection with the Training Colleges, the University Local Examinations, and the Oxford University Extension Movement, and a contribution of £150 towards the salaries of each of the Geographical Lecturers at the Universities of Oxford and Cambridge. I am happy to be able to report that our efforts to promote geographical education in the first of these great national institutions are being crowned with success, thanks to the enlightened views now prevailing there, to the powerful assistance of the Warden of Merton and other friends in high place, and to the zeal and high intelligence of Mr. Mackinder, who is rapidly winning not only golden opinions for himself, but an excellent place for his science on the banks of the Isis. Negotiations are now in progress which will, I hope, result in the establishment of a Travelling Scholarship at the joint expense of our Society and of the University of Oxford. Our Fellows will, no doubt, have observed that efforts are being made to have the Ordnance Survey pushed on more rapidly than hitherto, as well as to make more generally accessible to the public the results of so much well-directed labour. They will approve, I feel sure, of the Society's assisting these efforts in all legitimate and reasonable ways."

The President then proceeded to review the exploring work of the year, most of which has already been dealt with in NATURE.

PARKA DECIPIENS.[1]

THIS very interesting fossil is derived from various localities in Scotland, all of which are believed to be Lower Devonian. It was first described in 1831 by Dr. Fleming, and since then has been noticed on several occasions, and variously regarded as the spawn of Mollusca or Crustaceans, and as of vegetable origin.

The material upon which the present observations are based was collected by Mr. James Reid[2] and Mr. Walter Graham, both of whom have offered many valuable suggestions as to the probable nature and affinities of the fossil. As found, the *Parka decipiens* usually consists of oval masses bearing rounded impressions or disk-like bodies of carbonaceous matter. Associated with these are also stems and linear leaves of two dimensions, and a third form having a general resemblance to Pachytheca, which is found in the same beds, and differing from it in having a more discoid form, and being devoid of structural markings.

The authors show that the fossil is probably a rhizocarp allied to *Pilularia*, and that there are at least three forms recognizable, of which one is referred to the species, and the other two to varieties. The views thus stated are based upon differences of size and upon the fact that certain of the disk bodies show spores of two kinds, and in some cases prothalli in various stages of development, all derived from the same sporocarp.

The paper is illustrated by a plate of figures.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—In the list of the Mathematical Tripos (Part II.) Mr. Bennett, of St. John's, the Senior Wrangler, Mr. Crawford, of King's, the fifth Wrangler, and Miss Philippa G. Fawcett, "above the Senior Wrangler," are placed in the first division of the First Class.

SCIENTIFIC SERIALS.

THE *American Meteorological Journal* for May contains the following articles:—Cold waves, by Prof. T. Russell. In the report of the Chief Signal Officer for 1889, he expressed the view that the origin of cold waves was due to mixture of upper and lower air causing cooling of the layer next to the ground. On further examination of the subject, in connection with the observations at mountain stations, he admits the incorrectness of those views, and states that, while it is essential to connect the low temperature and high pressure in some way, the cooling of the ground by radiation, and of the air by contact and conduction, will not completely explain the cause of cold waves.—How could the Weather Service best promote agriculture?, by M. W. Harrington. The American Weather Service has hitherto devoted itself more particularly to the interests of commerce, while the State Services have had the interests of farmers more distinctly in view. What the farmer wants to know is, where and when a local shower will fall. While the complete solution of this problem may be impossible, the approximate solution lies in the multiplication of local forecasting stations, and in the intelligent use of the indications of the Central Office, combined with the indications which he can himself observe. The author recommends more attention to climatology as distinct from weather changes, and to the relations between plants, soil, and meteorology.—Is the influenza spread by the wind?, by H. H. Hildebrandsson. This is a translation, by the author, from an article in the Journal of the Medical Society at Upsala, and is, practically, a reply to an article in NATURE of December 19, 1889, where it is stated that the malady is probably spread by the wind. The author shows, by a map and table, the places and dates at which influenza occurred in Sweden, from inquiries of medical men. The result of the research goes to show that the influenza is propagated by infection, that it is conducted from place to place through human circulation, and that the time of incubation is two to three days. The state of the weather seemed to have no influence on the spread of the malady; in fact, it raged with the same severity in countries possessing very different climates, and during very different weather conditions.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 4.—"On a Determination of the Mean Density of the Earth and the Gravitation Constant by means of the Common Balance." By J. H. Poynting, D.Sc., F.R.S., Professor of Physics, Mason College, Birmingham.

---

[1] "Notes on Specimens from the Collections of Messrs. Graham and Reid," by Sir Wm. Dawson, LL.D., F.R.S., and D. P. Penhallow, B.Sc., F.R.S.C. Abstract of a paper read before the Royal Society of Canada, May 1891.

[2] Mr. Reid acknowledges his indebtedness to Mr. Langlands, the lessee of Myreton quarries, whose kind permission to examine these quarries was so freely granted.

In a paper printed in the Proceedings of the Royal Society, No. 190, 1878, an account was given of some experiments undertaken in order to test the possibility of using the common balance in place of the torsion balance in the Cavendish experiment. The success obtained seemed to justify the continuation of the work, and this paper contains an account of an experiment carried out with a large bullion balance, in place of the chemical balance used in the preliminary trials. The work has been carried out at the Mason College, Birmingham.

The Principle of the Experiment.—The immediate object of the experiment may be regarded as the determination of the attraction of one known mass on another. If two spheres, of masses M and M′, have their centres a distance d apart, the attraction is, according to the law of gravitation, GMM'/d^2, where G is the gravitation constant. Astronomy justifies the law in certain cases as regards M'/d^2, but does not give the value of G or M, except in the product GM. To find G we must measure GMM'/d^2 in some case in which both M and M′ are known. Having found G, we may determine the mean density of the earth, for, assuming that it is a sphere of radius R, the weight of any mass M′ at its surface is

$$G \times \tfrac{4}{3}\pi R^3 \Delta M'/R^2$$
$$= \tfrac{4}{3} G\pi R \Delta M'.$$

But if g is the acceleration of gravity the weight of M′ may be expressed as $M'g$. Equating these values, we get

$$\Delta = \tfrac{3}{4}\frac{g}{G\pi R}.$$

Method of Using the Common Balance.—With the length of beam used (about 123 cm.) a differential method was applicable, in which the attraction on the beam was eliminated. Two spherical masses of lead and antimony, about 21 kilos. each, were hung from the two arms of the balance, so that their centres in the first position were about 30 cm. above the centre of a large attracting mass, a sphere of lead and antimony about 153 kilos., placed on a turntable, so that it could be brought in turn immediately under either of the suspended attracted masses. A balancing mass of half the weight, and at double the distance from the centre of the turntable, was found necessary, so that the centre of gravity should be in the axis of rotation. Before this was used, the ground level was seriously altered by the rotation of the turntable. The attraction of the balancing mass was calculated and allowed for.

The alteration in the weights of the attracted masses, due to the motion of the attracting masses from one side to the other, was the quantity to be measured. When this was determined in the lower position of the attracted masses they were raised to about double the distance, and the attraction again determined. The difference eliminated the pull on the beam, suspending wires, &c. To lessen the effect of want of homogeneity or sphericity in the masses, or of want of symmetry in the turntable, the masses were all inverted and changed over each to the other side, and the weighings repeated.

The position of the beam was determined by the reflection of a scale in a mirror used with "double suspension." The mirror was suspended by two silk threads, one attached to the end of the ordinary pointer about 60 cm. below the central knife edge, the other parallel to it, being attached to a fixed support. The mirror turned through an angle about 150 times as great as that through which the beam turned, and one scale division corresponded to an angle of tilt in the beam of about 2/15ths of a second.

The value of a scale division was determined by the use of two equal riders which could be placed on or taken off wire frames representing the scale pans of a small subsidiary beam, 2·5 cm. long, fixed parallel to and at the centre of the large beam. When one rider was placed on one supporting frame the other was at the same instant lifted off the other frame.

The balance was left free throughout a series of weighings, and no moving parts of the apparatus were connected with the case.

The values obtained are as follows:—

$$\text{The gravitation constant } G = \frac{6{\cdot}6984}{10^8}.$$

$$\text{Mean density of the earth } \Delta = 5{\cdot}4934.$$

In the paper a description is given of a new form of cathetometer used to measure the diameters of the masses.

"Quadrant Electrometers." By W. E. Ayrton, F.R.S., J. Perry, F.R.S., and W. E. Sumpner, D.Sc.

In 1886 it was noticed, on continuously charging up the needle of Sir William Thomson's bifilar suspension quadrant electrometer No. 5, made by Messrs. White, of Glasgow, and in use at the laboratories at the Central Institution, that the deflection of the needle, when the same P.D. (potential difference) was maintained between the quadrants, instead of steadily increasing, first increased, and then diminished; so that, both for a large charge on the needle as well as for a small, the sensibility of the instrument was small. A similar effect had been described by Dr. J. Hopkinson, in the Proceedings of the Physical Society, vol. vii. Part 1, for the previous year, and the explanation he gives of this curious result is, that if the aluminium needle be below the centre of the quadrants, the downward attraction of the needle, which varies with the square of the needle's charge, increases the pull on the bifilar suspension, and so for high charges more than compensates for the increased deflecting couple due to electrical action. On raising, however, the needle of our electrometer much above the centre of the quadrants, the anomalous variation of sensibility of the instrument with increase of charge in the needle did not disappear; and even when the needle was raised so that it was very close to the top of the quadrants, and when, if Dr. Hopkinson's explanation were correct, the sensibility (or deflection corresponding with a given P.D. between the quadrants) ought to have been very great for a large charge on the needle, it was, on the contrary, found to be small.

The needle was carefully weighed, with the platinum wire attached and the weight dipping into the acid, and a calculation was made as to the magnitude of the effect that should arise from the change of the pull of the fibres due to any upward or downward attraction of the needle by the quadrants. This calculation showed that for a P.D. of 3000 volts between the needle and the quadrants, the amount of such attraction was quite unable to account for the observed diminution of sensibility with large charges in the needle. Dr. Hopkinson says in his paper, "Increased tension of the fibres from electrical attraction does not therefore account for the whole of the facts, although it does play the principal part." The experiments that we made at the end of 1886 and beginning of 1887, confirmed by the calculation above referred to, proved that, at any rate in our specimen of the quadrant electrometer, the principal part of the anomalous action was not caused by an increased tension of the fibres, and that therefore some other cause must be looked for to explain the observed results.

We therefore decided to make a complete investigation of the laws connecting the variation of the sensibility of the instrument with the potential of the needle, the distance between the fibres, the distance between the quadrants, and the position of the needle.

The results of the investigation, briefly summed up, are as follows:—

(1) The quadrant electrometer, as made by Messrs. White, although it may be carefully adjusted for symmetry, does not usually even approximately obey the recognized law for a quadrant electrometer when the potential of the needle is altered.

(2) The peculiarities in the behaviour of the White electrometer are due mainly to the electrical action between the guard tube and the needle, and to the slight tilting of the needle that occurs at high potentials.

(3) By special adjustments of the quadrants of the White electrometer, the sensibility can be made to be either nearly independent of the potential of the needle, or to be directly proportional to the potential, or to increase more rapidly than the potential of the needle.

(4) By altering the construction of the instrument, as described, the conventional law for the quadrant electrometer is obtained without any special adjustment of the quadrants beyond that for symmetry, and the instrument is rendered many times as sensitive as the specimen we possess of the White pattern.

Linnean Society, June 4.—Prof. Stewart, President, in the chair.—After nominating as Vice-Presidents Mr. A. W. Bennett, Dr. Braithwaite, Mr. F. Crisp, and Dr. St. G. Mivart, the President took occasion to refer to the loss which the Society had sustained by the recent death of a Vice-President, Prof. P. Martin Duncan, F.R.S. His genial presence at the meetings, no less than his valued contributions to the publications of the Society, would, he felt sure, be missed by everyone.—Sir Walter Sendall, who was present as a visitor, exhibited a curious cocoon of a moth belonging to the genus *Tinea*, and made some remarks on its construction and peculiar coloration.—The President exhibited a case of Lepidoptera and Coleoptera, which he had selected to illustrate some of the more notable secondary sexual characters in insects, and made some interesting explanatory observations.—Dr. John Lowe exhibited some eggs of *Mantis religiosa* which he had found adhering to the underside of stones on mountain-sides in the Riviera.—On behalf of Mr. F. J. Hanbury, Mr. W. H. Beeby exhibited and made remarks on a sterile form of *Ranunculus acris*, on which some criticism was offered by Prof. H. Marshall Ward.—A paper by Mr. M. C. Potter was read, on diseases of the leaf of the cocoa-nut tree. The specimens examined had been received from Ceylon through Dr. Trimen, and in Mr. Potter's opinion the diseases noticed were referable to three causes—namely, to the rays of the sun, to the ravages of insects, and to Fungi. These were separately considered, and descriptions were given of the different appearance which the leaves, thus variously affected, presented. A discussion followed, in which Prof. H. Marshall Ward criticized in some detail the observations which had reference chiefly to Fungi.—Two papers followed by Dr. P. H. Carpenter, on some Arctic *Comatulæ* and on some *Crinoidea* from Madeira, upon which Mr. W. Percy Sladen offered critical remarks.—The President then gave an abstract of a paper which he had prepared on a hermaphrodite mackerel, and exhibited the specimen on which his observations were founded, referring also to the recent cases of hermaphroditism in the trout and cod which had been brought to the notice of the Society. A commentary by Prof. G. B. Howes brought the proceedings to a close.

EDINBURGH.

Royal Society, May 18.—The Hon. Lord Maclaren, Vice-President, in the chair.—Dr. Buchan read a paper on the barometer at Ben Nevis Observatory, in relation to the direction and strength of the wind. In arranging the results, Dr. Buchan has referred the direction of the wind to sixteen points of the compass, although the observations are actually made with reference to the thirty-two points. The readings of the barometers at the high level and the low level stations, when reduced to sea-level, exhibit marked differences dependent upon the direction of the wind. The investigation extends over the period of nine months commencing in August last. During that time, all the very high winds have been from the east-south-east and the south-east, these being the directions in which the wind blows freely along the top of the mountain to the Observatory. In eleven cases the wind from these directions attained a speed of 120 miles an hour or more; and the (reduced) barometer at the high level station read about one-sixth of an inch lower than the instrument at the low level station. In no other direction was a higher velocity than 70 miles an hour noted; and in the directions from west to north-north-west, east, and east-north-east, the velocity was never greater than 30 miles an hour. With northerly winds the instruments at the top of the mountain record a much lower speed than that which, from observations of the drift of the clouds, is seen to be reached at a small height above the top of the mountain. The cause of this comparative calm immediately at the top is the impact of the air upon the face of the cliff which lies to the north of the Observatory. The stream lines are thus suddenly deflected upwards. In such cases the depression of the barometer is about three times as great as that which occurs with an equally strong wind from other directions, and indicates the formation of a region of low pressure around the Observatory. A peculiar result which is observed with other directions of the wind is that the (reduced) high level barometric reading exceeds the (reduced) low level reading when the wind blows at about the rate of 5 miles an hour. The reverse is always true when the speed of the wind exceeds that rate, on the one hand, or is extremely small, on the other. This seems to indicate an increase of pressure in air-currents which ascend the mountain, and so may explain the fact that the top of the mountain is frequently clear, while dense cloud is being constantly formed at a short distance above it.—Dr. J. Berry Haycraft gave an account of some experiments which show (1) that the displacements of the heart, which since Harvey's time are supposed to take place with every contraction, do not really occur in the unopened chest, and (2) that the cardiogram has been misinterpreted by physiologists. It is usually supposed that, during each contraction, the heart twists towards the right while its apex moves forward, and, pressing against the wall of the chest, causes the "apex beat." Again, it has been supposed by some that, during expansion, all diameters of the heart are not increased, but that, on the contrary, one diameter is diminished in length. Dr. Haycraft's experiments show that all diameters are increased during expansion, and that all are diminished during contraction. They show also that the motions, above described, do not occur in the unopened chest. The heart, in order that it may be observed in the opened chest, is necessarily separated from its attachments and falls towards the back of the chest (the animal operated upon being supposed to be placed upon its back). During expansion, the heart becomes flaccid, and so is flattened against the back of the chest. The first effect of the stiffening which occurs during the muscular contraction is therefore an elevation of the heart, against gravity, towards the front of the chest. Similarly, if the animal be turned upon one side, the heart, during contraction, moves towards the upper side of the chest; and the "beat" can even be made to take place towards the back. In the unopened chest, the heart on the whole remains in position during contraction, and therefore its boundaries move from the chest walls. But the cardiogram, as usually interpreted, shows that the chest wall is thrown outwards by the impact of the heart during contraction. Dr. Haycraft asserts that this is due to deformation of the heart by pressure of the chest wall when the button of the cardiograph is pressed against the exterior of the chest. The first effect of the muscular contraction and stiffening of the heart is therefore increased pressure against the chest-wall, which gives rise to the up-stroke of the cardiogram. When the cardiograph is made as light as possible, the up-stroke is greatly diminished; but it never entirely vanishes, because the flaccid heart is always slightly distorted by the chest-wall even when the cardiograph is not pressed against it. Dr. Haycraft further shows that the sinuosities, which always appear to a greater or less extent on the cardiogram, are not due to peculiarities in the action of the heart, but are instrumental in their origin, being caused by oscillations which result from the inertia of the cardiograph.—Dr. Hugh Robert Mill read a paper on the physical geography of the Clyde sea area, and the salinity and chemical composition of its waters. He described records, and discussed observations, made by himself and other members of the staff of the Scottish Marine Station. The observations dealt with extend over a period of three years, and their reduction has occupied, in addition, the greater part of two years. In the first part of the paper the author gives a detailed description, illustrated by a bathymetric chart, of the configuration of the Clyde sea area, with a special account of the various loch basins. The area and volume of each of these depressions are calculated, and the area of land which drains into each of them is measured on accurate maps. The rainfall is discussed in detail, and the river discharge is calculated indirectly, tables being drawn up to show the volume of rain water which flowed into each of the lochs during each month of the year. The month of maximum rainfall over most of the area is January, that of minimum rainfall is May. The whole sea area is conveniently divided into two parts—the seaward, of great extent, bordered with comparatively low ground, and lying in a region whose average rainfall is 44 inches; and the landward, made up of deep narrow loch basins, bordered by lofty mountains, and occupying a region whose average rainfall approaches 60 inches. In the latter part of the paper the positions of thirty-four stations (twenty-seven in the landward, and seven in the seaward division), at which observations were regularly made, are described. The method of collecting water samples, and the method of determining the density by means of a *Challenger*-type hydrometer, are given in detail. A record of 850 determinations of density made during twelve trips, which extended over two years, are given in an appendix. Twenty tables are given, which show the relations of salinity to configuration, tides, and rainfall, and which exhibit the relative amounts of pure sea-water and of fresh-water which were present in each of the divisions of the sea area at certain selected times. It was found that the amount of salt present in the water of the Clyde sea area varies with the season, the water being, as a rule, freshest in February, one month after the maximum rainfall, and saltest in July or August, two months after the minimum rainfall. The surface water exhibited the greatest changes, the seasonal variations being more regular at greater depths. Even at the head of lochs 50 or 60 miles distant from the open sea the percentage of pure sea-water present was rarely less than 88; the fresh river-water which poured in in enormous volume after heavy rain rapidly mixing with the sea-water, which was constantly renewed by the tide. So rapid and complete is this process of interchange, that the amount of river-water actually present diluting the water of the Clyde sea area is much less than the amount which passes through it every year, and is not equal to half of the average rainfall. In an average year 1·25 cubic miles of water, 97·5 per cent. of which is pure sea-water, and 2·5 per cent. fresh-water, enters the area at every tide; and a slightly greater amount is withdrawn, the whole being freshened a little so as to contain 2·7 per cent. of its volume of fresh-water. The great saltness of the deep water of the sea lochs, on which their importance as fishing-grounds depends, appears to be due to two causes. One of these is the thorough mixture of the tidal water from bottom to surface as it pours across the shallow bars at the mouths of the lochs. The saltest surface water was always found at flood-tide, off Otter Spit in Loch Fyne, where the salt water welled up from beneath in consequence of the rapid shoaling of the channel. Another cause of thorough mixture is the influence of the wind, which seems to set up a complete vertical circulation. Thus if wind is blowing strongly down Loch Fyne, the freshened surface water is driven out of the loch, and very salt water rises at the head of the loch to take its place. In a down-loch wind the surface water is almost always saltest at the head of the loch, and diminishes in salinity towards the open sea. The paper concludes with a summary of the chemical composition of the water.

Paris.

Academy of Sciences, June 8.—M. Duchartre in the chair.—On the currents which give rise to cyclones, by M. H. Faye. The views held by Dr. Hann and Prof. Ferrel concerning cyclones and anticyclones are compared. The author believes that cyclones, but not anticyclones, are dynamical phenomena, with which local circumstances of temperature have nothing to do, and he shows that they depend on the general movements of the atmosphere due to Polar cold and equatorial heat. On this point, therefore, M. Faye agrees with Dr. Hann.—Note on the presence of the *Kophobelemnon* in the waters of Banyuls, by M. H. de Lacaze-Duthiers.—The mastodon of Cherichira, by M. Albert Gaudry.—A new chemical balance for rapid weighings, by M. Victor Serrin.—Partial eclipse of the sun on June 6, observed at Nice, by M. Perrotin. With a power of 280, the time of first contact was observed to be 5h. 54m. 26s.; and of second contact, 6h. 53m. 26s. Nice mean time.—Observations of the new asteroid discovered at Nice Observatory on May 16, by M. Charlois. The observations are for May 16 and 25.—Observations of Brooks's comet (1890 II.), made with the great equatorial of Bordeaux Observatory, by MM. G. Rayet and L. Picart. Twenty-three observations for position were made between February 3 and April 29. The comet has been followed from March 27, 1890, to April 29, 1891.—On the theory of shooting-stars, by M. Callandreau. The author develops the equation of condition to be fulfilled by radiant-points belonging to the same family of meteors. According to Mr. Denning's observations, the Perseid radiant-point moves towards the east during the period of activity, a fact indicated as probable by Leverrier in 1871. This is in conformity with the equation of condition, which shows that if the latitude of a radiant-point varies slightly the longitude increases.—On two systems of differential equations, of which the hyperelliptic functions of the first order form the integrals, by M. F. Caspary.—Determination of the mechanical equivalent of heat, by M. Constantin Miculesco. The method adopted was similar in principle to that used by Joule. Thirty-one experiments made with this apparatus gave very accordant results, and the mean of them all give 426·7 as the mechanical equivalent of a calorie in kilogram-metres.—Dielectric properties of mica at high temperatures, by M. E. Bouty. The principal result of the research is that the dielectric constant is almost invariable for rapid alternations.—Application of the principle of the transmission of pressures to widely separated telephone transmitters, by M. P. Germain.—Action of ammonia on some compounds formed with halogen salts of mercury, by M. Raoul Varet. The author has studied the action of ammonia on compounds formed with mercury iodide and metallic cyanides, with the idea of determining the *rôle* of certain compounds of ammonia in double decompositions.—On a new method of preparing silicon chloro-iodides, by M. A. Besson.—On three cases of free development observed in Bryozoas ectoproctæ, by M. Henri Prouho.—On the locusts of Algeria, by M. Charles Brongniart.—On the morphological nature of the phenomena of fecundation, by M. Léon Guignard. It results from the observations that the phenomenon of fecundation consists not only in the copulation of two nuclei of different sexual origin, but also in the fusion of two protoplasms, also of different origin, and represented essentially by the directing spheres of the male and the female cell.—On the inclosures of nephelinic syenites found in the middle of phonolites from Höhgau and in some other beds; conclusions to be drawn from them, by M. A. Lacroix.—Observations of the parallelism of Upper Cretaceous strata of the Western Pyrenees (Lower Pyrenees and Landes), by M. Jean Seunes.—The sympathetic nerve of accommodation for the observation of distant objects, by MM. J. P. Morat and Maurice Doyon.—Researches on the existence of parasitic organisms in diseases of the crystalline lens of the eye of man, and on the possible *rôle* of these organisms in the pathology of certain ocular affections, by MM. Gallippe and L. Moreau.—On the employment of carbon bisulphide dissolved in water for the destruction of Phylloxera, by M. A. Rommier.

EDUCATIONAL ASPECTS OF FREE EDUCATION.

An innocent outsider would naturally suppose that the discussion on a proposal for free education would turn chiefly on educational and social considerations. So long as the question was of merely academic interest, this was, to a large extent, the case. It is true that strong Churchmen viewed with distaste a change which might increase the growing difficulty, found by voluntary school managers, of making both ends meet, or might possibly even sweep them off the board altogether, and that the enthusiasm of many partisans on the other side for the remission of fees was heightened by the hope that such a measure would give a new impetus to the formation of School Boards. But, on the whole, the disputants made at least an attempt in public to discuss the matter in its bearings on the child, the teacher, and the parent. The overburdened parent, the pauperizing effect of partial remission, the child kept from school because of his parents' poverty, the teachers converted into tax-collectors—these were the stage properties of the one party; while the stock-in-trade of the other side included the sacred necessity of guarding "parental responsibility," and the assertion that no one values what he does not pay for, and that to tax the hard-earned savings of the respectable middle-class to free the education of the children of the worthless and unthrifty was a Socialistic proposal of the crudest kind.

We now find that most of this talk was pure cant. It ceased to be heard from the moment when free education became a practical party question. To outward appearance the contest over the Bill has become a kind of Jerusalem race—everyone wishing to leave to someone else the unpleasant task of formulating the criticisms with which he secretly sympathizes, but to which fear of his constituents prevents him from giving utterance.

If we could induce the parties to break through this conspiracy of agreement, we should find that, with a few exceptions, the point on which the advocates feel most keenly is the possibility of using the Act as a lever either to destroy or to perpetuate for ever the voluntary school system. In spite of the apparent calm, the battle between the supporters of School Boards and voluntary schools is raging fiercely below the surface; and most of the amendments put down for the Committee stage are certain to represent attempts, more or less open or disguised, to wrest the provisions of the Act to suit the purposes of one or the other party.

It must be confessed that this is to a great extent natural. The Act of 1870 was a compromise: the present Bill virtually reopens the question, and it is felt that, whatever be the logic or want of logic in the argument that Imperial grants should involve local control, the time when large additional grants are being made to voluntary schools is the time, *if ever*, to drive home the question of popular management. We do not, then, quarrel with those who feel that the opportunity must not be lost of raising this question; indeed, we should respect them more if they raised it more openly. But we do protest against the almost total omission of all educational considerations in the arguments used on both sides.

It is time that the third party to the dispute—the real friends of education—made themselves heard. Their one object is to see that the educational benefits of the measure should be maximized, and the incidental evils minimized. They ask what is to be demanded in the shape of increased efficiency in return for a new grant of £2,000,000 to school managers. Is a great part of it to be allowed to be absorbed by the reduction of private subscriptions and rates, or is it to be used to improve the children's education, and make it a better preparation for their future industry?

In the rural districts, the grant in lieu of fees will almost universally be in excess of the income now received from fees. There will therefore be a surplus in the hands of the managers, or manager—for very often these schools are in the hands of one man. Where will this surplus go? In our opinion some method ought, if possible, to be found of "ear-marking" it for education rather than for subscribers' pockets. If this were done, nearly the whole of the rural schools of England might be raised in character. It would be possible, for example, to introduce, with the aid of the new surplus, some simple teaching in agricultural subjects, such as is recognized in the Code, but is at present a dead letter; for the increased grant would be quite enough to pay a competent travelling teacher to give such instruction in a group of schools. If there were universal county or district school authorities, it might be well to hand over the surplus grant into their hands, to be used solely for the improvement of the various schools on whose account it was paid. As, unfortunately, our organization is piecemeal, we are forced to deal direct with each school, and we can therefore only appeal to public-spirited managers to take care that the children for whose education they are responsible reap the full advantage of every penny which they receive over and above the present fees charged. It is to be feared, however, that in many cases the managers are at the mercy of their subscribers, and many of them would probably now welcome the proposal made by the Bishop of London, but foolishly rejected by his clerical friends on the late Royal Commission—that a certain minimum of private subscriptions should be required by law in the case of every voluntary school. If such a provision were in force, school managers in the country would be saved many anxious forebodings at the present time.

The second point in the Bill on which educational reformers should fix their attention is the limitation of the benefits to children between five and fourteen. The lower limit need not trouble us, and may be left to be worried by the "poor man's" numerous friends. But the upper limit should be resolutely opposed. It is quite true that at the present time it is of comparatively little importance—only affecting some few thousands of children. But if one of the great objects of educational policy is to lengthen the period of school life, the handful of children at elementary schools above fourteen should certainly not be fined for staying there; if anything, they should receive scholarships to enable them to do so. In our opinion, moreover, ex-seventh standard children (who are not for the most part touched by the present Bill) should be also admitted free, or at least sufficient scholarships should be provided to enable any poor child who has passed the standards to continue his education either in the school or elsewhere. We do not say that such scholarships should be universally provided out of the present grant, but they would be a most proper object to which to apply part of the surplus which will be handed to many schools over and above the fee equivalent. These considerations suggest another possible way of dealing with the surplus grants. The great object of those who are interested in the development of higher elementary, technical, and secondary education should be to strengthen instead of weakening the connection between primary and higher schools. It is to be feared that any provision for freeing elementary schools up to a certain point or a certain age, will tend to sever rather than to unite the two grades of schools, unless the flow between them is at the same time stimulated by the establishment of free scholarships or in other ways. A free (or partly free) elementary school is not the ultimate ideal. We want a free road kept open to the University. Is it too late to throw out the suggestion that school managers receiving a fee-grant in excess of the amount previously received in fees should be required to use the surplus for an object akin to that contemplated by the main provisions of the Bill—viz. the extension of free education for selected scholars beyond the narrow limits of the primary schools, in other words the provision of continuation scholarships? Up to a short time ago it would have been replied that in many cases there were no higher institutions accessible, but the application of the Local Taxation grant to technical and secondary education is fast changing all that, and a proposal which a few years since would have been unfeasible is now well within the range of practical politics.

DIFFERENTIAL AND INTEGRAL CALCULUS.

Differential and Integral Calculus, with Applications. By Alfred George Greenhill, M.A., F.R.S. Second Edition. (London: Macmillan and Co., 1891.)

PROF. GREENHILL is known to the academic world as an accomplished mathematician who has powerfully helped to advance certain branches of applied mathematics; he is also known to the readers of NATURE as a friend (militant) of the practical man. We say at once, in all sincerity, that we sympathize with Prof. Greenhill in both his capacities. The volume on the infinitesimal calculus now before us, although professedly a second edition, is in reality a new work, addressed to the special needs of the practical man by his mathematical friend Prof. Greenhill.

Of many of the author's didactic innovations we highly approve. The treatment of the differential and integral calculus together from the very beginning is a piece of sound method, the introduction of which has been delayed merely by the bad but not infrequent practice of separating the two as examination subjects. The introduction of the hyperbolic functions to systematize the integrations which can be performed by means of the elementary transcendents, has been, as we can testify from experience, a great help in elementary teaching. The admirable "chapter in the integral calculus" which was published separately in an extended form some years ago, and is now condensed and simplified in a separate chapter at the end of the work under review, is the most important addition to the teaching material of the integral calculus that has been made for a long time; that chapter alone is worth the price of Prof. Greenhill's book. The plan of drawing the illustrations of the subject from departments of pure and applied mathematics with which the learner may afterwards have to do is also excellent. Finally, there blows through our author's pages that inimitable freshness which emanates from the man who is familiar with much that is newest and best in his day, who does not merely make extracts from books, but who speaks of things in which he has taken a part. This freshness can only be compared to that agreeable odour which inland people tell us comes from mariners and others who cross the sea from strange lands. Like these same mariners, our author produces from his pockets strange and puzzling curiosities, such as reciprocants, tide predicters, Schwarzian derivatives, Mehler's functions, to delight and to dazzle the learner. It is true he tells but little of these things; still, it is pleasant to look at them; and they make us happy under our present toil by leading us to think that we too may one day visit the country where these pretty things are at home amidst their proper surroundings.

Where there is so much to praise we are truly sorry to insinuate the bitter drop of blame; but, much as we love and follow Plato, something must be conceded to truth. In the first place, we think that in this second edition the introduction of heterogeneous illustration has been overdone. The fundamental rules of the infinitesimal calculus are really very few in number, and the practical man's friend would do well to impress that upon him at the outset, instead of scattering these principles through a large volume, and overlaying them with thick masses of disconnected application, to such an extent that poor Mr. Practical-Man is in danger of losing his tools among the shavings, or, to use a metaphor which Prof. Greenhill's pupils might prefer, of not seeing his guns for smoke. Prof. Greenhill must recollect that the man that sits down to read his book is not all possible practical men rolled into one, but *one* poor practical man—say, an engineer—who wants some knowledge of the infinitesimal calculus, and who will find many of the illustrations more indigestible than the principles of the calculus itself. Would it not be better for the practical man, as well as for any other man, to have the few leading principles of the calculus set before him with an adequate but moderate amount of illustration of a uniform geometrical kind, and not to be dazed by a flood of oracular statements about soap-bubble films, tide-predicters, &c., in the course of his initiation? Such digressions are most useful now and then in a lecture; they serve to give picturesqueness to the discourse, and help to fix the attention of the hearer: but we think that too many of them destroy the usefulness of a text-book, the object of which is quite different from the purpose of a lecture.

The matter we have just been criticizing may, perhaps, be held to be one of taste; and we cheerfully admit that much should be allowed to a writer of strong individuality. After all, we love to have the author in his book. There is another matter, of more importance, on which we would appeal to Prof. Greenhill. When a man, so able and unconventional as he, writes a book of 455 pages on the infinitesimal calculus, is it too much to expect that he will everywhere give a thorough discussion of its few fundamental principles, that he will rigorously prove what he professes to demonstrate, and honestly point out what he assumes without demonstration? We certainly expect him to root out of the subject every trace of the sham demonstration—that wily artifice of the coaching and examining days of our dear old *alma mater*—which used sometimes to be dignified by the name of the "short proof." This used, to be employed when we had on hand the establishment of some proposition which was not universally true (although usually so enunciated), or which had exceptions too tedious to enumerate in an examination. The method was to make a kind of *précis* containing as few words of intelligible English as possible, but a considerable sprinkling of ingeniously constructed but unexplained symbols and formulæ; so that an examiner of average conscience, suspecting that the truth was not there, might nevertheless, without mental distress, make believe that it *was* there, and award the coveted marks.

We complain that Prof. Greenhill should countenance the slipshod exposition of elementary principles which is the bad feature of so many of our English mathematical text-books. Having started his furrow, he should have ploughed to the end. He may retort that he has adhered to the traditional usage out of consideration for the weakness of the practical man, who abhors sound logic quite as much as his academic brother. Cruel consideration for the practical man! for what *he* wants above all is a firm grasp of the fundamental principles of the calculus; he has rarely any use for the analytical house of cards, composed of complicated and curious formulæ, which the academic tyro builds with such zest upon a slippery foundation.

It would take up too much of the columns of NATURE to give all the examples that might be adduced of the laxity we complain of. A few must suffice. We are told in § 1 that the "calculus to be developed is the method of reasoning applicable to variable quantities in a state of continuous change;" yet no definition or discussion of "continuity" is given: the word, so far as we can find, does not occur again in the first chapter, although it is the keynote of the subject. "Newton's microscope," for example, is quoted in § 9, as a proof of the theorem $Lt(\text{chord}/\text{arc}) = 1$; but the essential condition, "in medio curvaturæ continuæ," which makes it a proof (if proof be the word that describes its purpose) is omitted. Although the differential calculus is merely a piece of machinery for calculating, and calculating with limiting values, a limiting value is not defined; nor is there any discussion of the algebra of limiting values—a matter which has puzzled beginners in all ages, and which has stopped many on the threshold of the calculus. It is true that we are referred to Hall and Knight's "Algebra," but what we find there is little to the purpose, and certainly could never have been meant by its authors as a foundation for the differential calculus.

In § 16 we are given a quantity of elementary instruction, in the middle of which the trigonometrical functions are inadequately defined; but nothing adequate is said regarding the sense in which the many-valued functions $\sin^{-1}x$, $\cos^{-1}x$, &c., are continuous: and in § 25 the beginner is led by implication to believe that $d(\sin^{-1}x)/dx$ is always $+ 1/\sqrt{(1 - x^2)}$, and $d(\cos^{-1}x)/dx$ always $- 1/\sqrt{(1 - x^2)}$; although this is not so, and the point is one that is of the greatest importance in the integral calculus, and is a standing rock of offence for learners. In § 28 we have, reproduced "for the sake of completeness," the time-honoured "short proof" of the existence of the exponential limit, which proof is half the real proof *plus a suggestio falsi*. If the proper proof (a very simple matter) was thought too much for the reader, then it would have been better simply to tell him the fact, and not to corrupt his intellectual honesty by demanding his assent to a piece of reasoning which is not conclusive. § 31 is no better; what, for instance, *does* Prof. Greenhill mean, after proving that $\exp n = e^n$, where n is a positive integer, by saying, "and thence generally by induction, $\exp x = e^x$ for all values of x." It would scarcely be possible to write down a statement to which more exceptions could be taken unless "induction" is a misprint for "assumption."

The chapter on the expansion of functions is not satisfactory. We are first introduced to "a general theorem called *Taylor's theorem*, by means of which any function whatever can be expanded [in ascending powers of x]." Prof. Greenhill knows as well as we that there is no such theorem. No theorem ever to be discovered will expand in ascending powers of x, $1/x$, $\sqrt{x}$, $\log x$, or any function which has $x = 0$ for a critical point. Why does our author hide his light from the reader? Does it make the apprehension of Taylor's theorem any easier to enunciate it falsely? We are told in § 114 that "some functions, for instance $\sec^{-1}x$, ... cannot be expanded in an infinite series in ascending powers of x, because x must be greater than unity, and the expansion by Taylor's or Maclaurin's theorem would be *divergent*, and the theorem is then said to fail."

"This difficulty will be avoided if we can make the series terminate after a finite number of terms."

We would not advise the practical man to try to overcome the difficulty of expanding $\sec^{-1}x$ by the method thus indicated (use of Maclaurin's theorem with the remainder), because the result might be that the bond of amity struck in the preface between him and the author would be broken. All the king's horses and all the king's men will not get over this difficulty. Incidentally we are told in § 112 that a rigorous proof is given in treatises on trigonometry of the resolution into factors of $\sin\theta$ and $\cos\theta$. If standard English treatises, such as Todhunter, Locke, and Johnson, are meant, this is not true: the demonstrations they give are unsound. Mr. Hobson's article on trigonometry in the "Encyclopædia Britannica" is the only separate English treatise on trigonometry of which we are aware where a sound proof can be found.

When so many novelties of less importance are noticed, surely our author might have found a place for a reference to the theorem that puts the expansibility of a function in ascending powers of x in its true position, viz. Cauchy's theorem that every function is so expansible within a certain region surrounding $x = 0$, provided $x = 0$ be not a critical value. Considering the great importance of the fact, and its close connection with the applications of mathematics to physical problems, some mention might have been made of the importance of the critical points of a function in determining its value. A full discussion of such things is doubtless impossible in an elementary treatise; but the reader should at least be warned that what is given regarding the expansion of functions in power-series is a mere fragment of what is known on the subject. The tendency of Prof. Greenhill's chapter on the expansion of functions certainly will be to suggest to the mind of a beginner wrong general notions on the subject.

In § 126 we have two proofs given that

$$\partial^2 f(x, y)/\partial x \partial y = \partial^2 f(x, y)/\partial y \partial x,$$

both of them insufficient; for the one rests on the assumption that $f(x + h, y + k)$ can always be expanded in an integral h-k-power-series, the other on the assumption that

$$\underset{h=0}{\mathrm{L}} \ \underset{k=0}{\mathrm{L}} \chi(h, k) = \underset{k=0}{\mathrm{L}} \ \underset{h=0}{\mathrm{L}} \chi(h, k),$$

both of which propositions are liable to exception.

In the discussion of single and double integrals, no hint is allowed to reach the reader of the necessity of convergency as a condition of their having any meaning at all, of the precautions that must be observed in differentiating them, or in altering the order of integration, and so on. Still, the reader is given a proof of Green's theorem. What use this is likely to be to one ignorant of the fundamental character of the convergency and discontinuities of multiple integrals, upon which many of the most important applications of the theorem in question depend, it is not easy to see. Too much of the work before us bears, in fact, the character of a hurriedly written *précis* or syllabus of lectures; witness, for example, the oracular character of §§ 146, 151, 152, &c. Our author makes enormous demands on the intelligence of a beginner if he expects him to follow and understand exposition so elliptical.

One more example of the thing we complain of. In § 183 we are introduced to Fourier's series. No proof is given (none was to be expected in an elementary treatise) of the conditions under which the expansion is possible, but it ought to have been stated that there are such conditions. Moreover, the method given for the determination of the coefficients is a mere *memoria technica* for recollecting them. It has no demonstrative force, because, as the author must be very well aware, it is not unconditionally allowable to replace the integral of an infinite series (even if it be convergent) by the sum of the integrals of its separate terms. In order that this may be admissible, the series must be *uniformly* convergent.

Seeing that the world is very evil, and not to be mended in a day, we must put up with such things in the ordinary writer of English text-books, who caters for the victims of our manifold examinations; but in a pillar of mathematical society like Prof. Greenhill they are "most tolerable and not to be endured." A work with his name on its back, and the impress of his vigorous personality on its pages, will not remain long in a second edition. If he would be at once the friend of the practical man, and a well-deserver of the mathematical republic, let him, when the third edition is called for, reduce his elementary work to the compass of the first edition or less, and replace all half demonstrations by honest statements of fact; and let him, meantime, write a larger work, to which he can refer the elementary reader who takes for his motto, "*Thorough.*"

G. C.

THE GEOLOGY OF THE COUNTRY ROUND LIVERPOOL.

Geology of the Country around Liverpool. By G. H. Morton, F.G.S. Second Edition. (London: Philip and Son, 1891.)

IN this work Mr. Morton has entirely re-written the "Geology of the Liverpool District," first published in 1863, by the light of the various discoveries made since that time, and especially of the Geological Survey maps and memoirs. He has succeeded in making a compact and well-printed hand-book, which will be of great service to the students of the local geology. The area described extends to about 20 miles from Liverpool on every side, excepting the sea on the west. The strata which he describes range from the Upper Silurians of the Vale of Clwyd through the Carboniferous, Permian, and Triassic rocks, down to the recent alluvia. To a geologist the chapter relating to the Carboniferous rocks of North Flintshire and the Vale of Clwyd will be of great interest, as it shows the thinning off of the strata as they approach the ancient Carboniferous land of North Wales. The Carboniferous Limestone, over 3000 feet thick in North Lancashire, is reduced to 1700 feet in North Flint and the Vale of Clwyd; while the Yoredales and Millstone Grits, over 9000 feet thick between Clitheroe and Burnley, are represented by the Cefn-y-Fedw Sandstone, 370 feet. The Lower and Middle Coal-measures, too, of South-West Lancashire, 3180 feet thick, have dwindled down to no more than 1000 feet as they approached the Welsh Silurian Hills. It is therefore obvious that the Snowdonian area was dry land while the Carboniferous sea occupied the areas of Lancashire, Derbyshire, and Cheshire, and that it also overlooked the forest-covered morasses, now represented by the coal-seams of the same region in the Upper Carboniferous age. In the table of the rocks (p. 6) Mr. Morton gives 300 feet as the thickness of the Millstone Grit in South-West Lancashire. It is probably much more than this, and not much less than 2000 feet. Mr. Morton also, we may remark, understates the thickness of the Keuper Marls, which he puts down at 400 feet (p. 75). In the Lancashire and Cheshire plain it is 700 + feet, and is estimated by Prof. Hull at 3000 feet.

Mr. Morton, in dealing with the deep boring at Bootle, made in 1878, under the advice of the writer of this review, is mistaken in supposing that it was aimed at the water in the Permian Sandstone. It was intended to strike the water in the Lower Bunter Sandstones, and to draw upon the enormous area of water-bearing strata in the Lancashire and Cheshire plain, which have their outlet seawards between Prescot and the estuary of the Dee. It is very likely that the Permians are not represented under Liverpool. We expected to strike the Coal-measures at 1000 feet. The boring was successful, both from the geological and the engineering point of view. It proved that the Lower Bunter Sandstones below the top of the Upper Pebble-beds are more than 1300 feet thick, and that they are highly charged with water. This thickness is altogether without precedent, and Liverpool is to be congratulated upon being built upon so great a thickness of water-bearing Triassic rocks. Mr. Morton, should the work reach another edition, would do well to deal at greater length with the water-supply available from the Triassic strata. Mr. Boult has tabulated the well-sections, and all students of the geology of Liverpool would do well to examine his valuable tables.

We would call special attention to Mr. Morton's section—unfortunately, the work is not divided into chapters—on the origin of the estuary of the Mersey. While the river has been draining its present watershed from a period far more remote than the Pleistocene age, he holds that the estuarine portion is comparatively modern, dating probably not further back than post-Roman times. It would not, he argues, following Sir James Picton, have been neglected by the Romans, if it had then "presented the copious body of water which it does at the present day." There is no evidence that they did neglect it. The Manchester Ship Canal works have revealed the existence of Roman remains, probably the Veratinum of the anonymous geographer of Ravenna, on the banks of the Mersey close to Warrington, and Mancunium (Manchester) is on one of its tributaries. They used it, as they used all the rivers of Britain, for their own ends. Deva (Chester), the great port, and military centre of the north-west, was not far off, and amply sufficient for the western trade at a time when there were no ports in Ireland. The commercial importance of the Mersey is solely due to the trade with the New World. There was no reason why the Romans should have paid special attention to the estuary of the Mersey; and it was outside the system of their roads. Nor can the date, 1279, of the great inroad of the sea over the Stanlow Marshes, by which the Abbey of Stanlow, built upon a rock only 28·5 feet above O.D., lost much of its land, be taken as evidence of the modern formation of the estuary. The river swings to and fro at the present time, depositing silt here, and carrying away its banks there. In our opinion, therefore, the post-Roman origin of the Mersey is not proved. It is still less likely that it is the result of a local submergence, which has not affected Warrington and the adjacent area of Chester. As the evidence stands, the date of the estuary of the Mersey belongs to the same remote prehistoric period as the estuary of the Thames and of the Humber—certainly after the time of the boulder clays, and probably long before there were any written records in Britain. All three are later than the time of the submarine forest which, on the west of Britain, afforded shelter, not merely to our Neolithic ancestors, but to their domestic animals, such as the small shorthorn (*Bos longifrons*), the goat, and the dog.

W. Boyd Dawkins.

OUR BOOK SHELF.

Les Microbes, les Ferments, et ses Moisissures. Par le Dr. E. L. Trouessart. Deuxième Edition. Bibliothèque Scientifique Internationale. (Paris, 1891.)

This is not only an enlargement but a distinct improvement on the first edition. Chapters i. and ii., as in the first edition, give an excellent though short account of the morphology and physiology of fungi and of yeast. Although chapter iii. (on bacteria) is enlarged, we do not think it is sufficiently up to date; thus, for instance, on pp. 74 and 75, the author questions the existence of true flagella in bacteria, and states that their motility is essentially different from that of flagellate infusoria. Again, in the section in which putrid decomposition is described no mention is made of the entire tribe of Proteus, the essential microbe of putrefaction.

Chapters iv. and v. (pathogenic bacteria) are considerably enlarged, both as to text and illustrations. The rest of the book, chapters vi.–ix., does not differ in any essential respect from its predecessor.

On the whole, the book is very commendable as a concise text-book, well written and copiously illustrated, and as such deserves a high place in the literature of the subject.

Botanical Wall Diagrams. Size 31½ inches by 24 inches, printed in colours. (London: Society for Promoting Christian Knowledge, 1891.)

A first instalment of six of these diagrams is now published. The plants illustrated so far are: common elder, deadly nightshade, scarlet runner, hop, Virginia tobacco, and wild camomile. We do not know on what principle the selection has been made. It is rather a pity that, out of so small a number, two (deadly nightshade and tobacco) belong to the same natural order, and show no very essential structural differences. In time we hope that all the important orders will be represented. The drawings (executed by Engleder, of Munich) are quite artistic, and the colouring excellent. The diagrams are thus very pleasing as pictures, and at the same time the botanical details are correct.

If the series is continued as well as it has been begun, it ought to be a very useful help in the elementary systematic teaching of botany.

D. H. S.

Chambers's Encyclopædia. New Edition. Vol. VII. (London and Edinburgh: W. and R. Chambers, Limited, 1891.)

No one who has had occasion to refer to the new edition of Chambers's "Encyclopædia" can have failed to appreciate the care and ability with which it is being prepared. The editor has been fortunate enough to secure the co-operation of many eminent writers, and the information given in the various articles, speaking generally, is well up to date and presented in the way most likely to be convenient for students. We are here concerned only with the papers on scientific subjects, and these, in the present as in the preceding volumes, are in every way worthy of the place which has been assigned to them in the scheme of the work as a whole. Prof. P. G. Tait contributes a short but masterly paper on matter, and Dr. Buchan gives a clear and interesting account of meteorology. The essential facts about the Mediterranean are compressed into very small space by Dr. John Murray, who also writes on the Pacific. Prof. James Geikie deals with mountains and palæontology, and Dr. Alfred Daniell has a good popular article on optics, devoted mainly to the history of optical science. In an article on man, Mr. J. Arthur Thomson states very well some of the problems relating to human characteristics, the origin or descent of man, and the antiquity of the race; and the same writer sketches the career of Pasteur, and treats of mammals and parasites. Mimicry forms the subject of an excellent paper by Mr. E. B. Poulton. Of course, no subject is treated exhaustively, but the information given, so far as it goes, is sound, and ample enough for the purposes for which an encyclopædia is usually consulted.

Glimpses of Nature. By Andrew Wilson. (London: Chatto and Windus, 1891.)

Mr. Wilson does not profess to present in this book anything strictly new, or to give a full account of the various subjects with which he deals. Nevertheless, the volume may be of considerable value, for on all the groups of facts in which he is interested he is able to discourse brightly and pleasantly, and many of his short papers are well calculated to excite in the minds of intelligent readers a desire for more ample knowledge. The papers are reprinted from the *Illustrated London News*.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

The Fusing and Boiling Points of Compounds.

I herewith send you the translation of a note just presented for me by M. Berthelot to the Paris Academy, as you may see in the *Comptes rendus.* I have added two illustrations and a few words in italics. Gustavus Hinrichs.

St. Louis, May 8.

Statement of the General Law determining the Fusing and Boiling Points of any Compound under any Pressure, as Simple Function of the Chemical Constitution of the same. By Dr. Gustavus Hinrichs.

The atomic form of normal lineary compounds, such as the paraffins, alcohols, acids, is very nearly prismatic. All other serial compounds may be referred to these, either as isomerics or as substitution products. The boiling and fusing points of these latter are obtained from those of the former according to laws and processes published by me about twenty years ago, partly in my "Principles of Molecular Mechanics," 1874, and in Notes of the *Comptes rendus* for 1873 and 1875; *partly in papers of the Proceedings of the American Association for the Advancement of Science for* 1868. It remains, therefore, only to show how these fundamental points are determined for prismatic compounds.

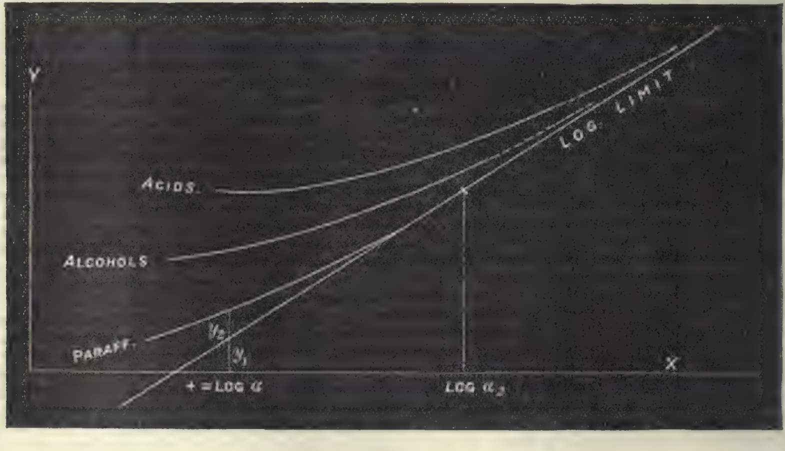

Fig. 1.

The boiling-point t of a prismatic compound consists of two distinct functions, namely—

$$t = y_1 + y_2 \quad . \quad . \quad . \quad . \quad (1)$$

where

$$y_1 = k_1(\log a - \log \alpha_1) \quad . \quad . \quad . \quad . \quad (2)$$

and

$$y_2 = k_2(\log \alpha_2 - \log a)^2 \quad . \quad . \quad . \quad . \quad (3)$$

The symbols α_1 and α_2 represent certain definite values of the atomic weight a of the compound, while k_1 and k_2 are constants.

For every value of the atomic weight a greater than α_2 the formula (1) is limited to $t = y_1$, which, according to (2), represents the straight line which I call the logarithmic limit, the ordinate being the boiling-point t, the abscissa x, the logarithm of the atomic weight $x = \log a$. For values of a less than the above limit α_2, the parabolic ordinate y_2, determined by (3), must be added to y_1, according to (1), in order to obtain the boiling-point.

Accordingly, the boiling-point curve of any homologous series of prismatic atom-form consists of a parabolic arc (3), tangent to the logarithmic limit (2), at the point determined by $a = \alpha_2$. The constant k_1 determines the inclination of the logarithmic limit, and k_2 may be called the parameter of the parabolic branch.

All compounds derivable by terminal substitution from normal paraffins have a common logarithmic limit, determined by $k_1 = 583°.75$ and $\alpha_1 = 72.78$, the pressure being 760 mm. Every individual homologous series of this great family of compounds is completely determined by the special values of the two constants α_2 and k_2. For example, the thirty-five normal paraffins C_nH_{2n+2} are determined by $\alpha_2 = 201$, and the parameter $k_2 = 200°$. For the monamines, the corresponding values are $\alpha_2 = 278$, and $k_2 = 225°$. I have determined these constants for all the important series. Furthermore, these values are themselves functions of the atom or radical which characterizes the head of the corresponding homologous series—*that is, H for the paraffins, H_2N for monomines, &c.*

If now the co-ordinate $z = \log p$, where p is the pressure of the saturated vapours, be laid off on the third rectangular axis the above given values belong to the plane XY determined by $p = 760$ mm. For the pressure $p = 15$ mm. the logarithmic limit is determined by $k_1 = 517°.0$, and $\alpha_1 = 113.81$. It will be noticed that its inclination towards the X axis is less, and that it intersects the same at a greater distance from the origin. The logarithmic limit surface, generated by the logarithmic limits for all pressures, is a hyperbolic paraboloid, fully determined by the above two lines for 15 and 760 mm. pressure.

For any liquid, the absolute temperature T of the boiling under a pressure of p atmospheres is determined by the same general law slightly specialized as follows:—

$$T = Y_1 + Y_2 \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

where

$$Y_1 = K_1[1{\cdot}4 + \log p] \quad . \quad . \quad . \quad . \quad . \quad . \quad (5)$$

and

$$Y_2 = K_2[\log \pi - \log p]^2 \quad . \quad . \quad . \quad . \quad . \quad (6)$$

The logarithmic limits of all liquids intersect in the same absolute zero point determined by $T = 0 = -273°$ C. and $\log p = -1{\cdot}4$. For each individual liquid this limit extends upwards to the critical point of the liquid, $p = \pi$ and $T = \theta$. For many liquids the critical point can be theoretically calculated, as well as the value of the parameter. It is understood that the parabolic curve is tangent to the logarithmic limit at the critical point.

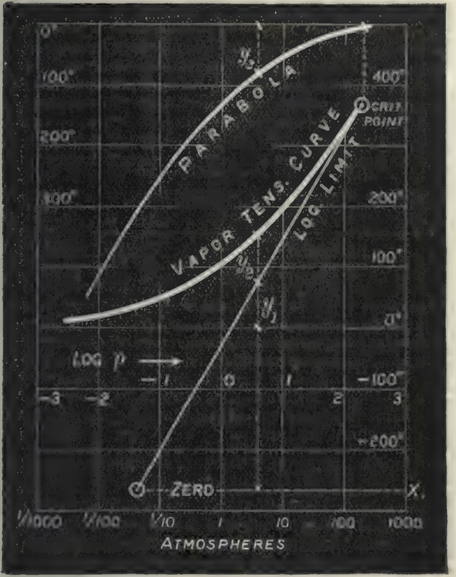

FIG. 2.

It hardly needs to be said that the tension of dissociation, and even the solubility of solids, are subject to the same general law.

The fusing points are obtained by simply changing the sign in (1) to

$$t = y_1 - y_2 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (7)$$

so that the parabolic curve will be placed below the logarithmic limit.

One of the most remarkable results of this research is the mechanical determination of the true position of the carbon atoms in organic serials, and the complete explanation of the difference in fusing point between compounds containing an even and odd number of carbon atoms.

It should also be understood that the change in fusing point produced by change in pressure is expressed by the same general law.

Putting $\log a = x$, $\log p = z$, and $\log \alpha = \xi$, $\log \pi = \zeta$, the formulæ (1) to (7) will become

$$t = y_1 \pm y_2, \quad y_1 = k_1(x - \xi), \quad y_2 = k_2(\xi_2 - x)^2 \; . \; (8)$$
$$T = Y_1 + Y_2, \quad Y_1 = K_1(z - \zeta), \quad Y_2 = K_2(\zeta_2 - z)^2 \; . \; (9)$$

These formulæ strikingly show the simplicity of the laws stated, and also determine the surfaces formed by the coordinates x, t, and y in general.

In subsequent notes special topics covered by this general law will be taken up, and the complete concordance of the law with the results of observations will be shown.

Porpoises in African Rivers.

IN reference to Mr. Sclater's letter in NATURE of June 11 (p. 124), the following may be interesting to your readers:—

The skull of a Delphinoid Cetacean from Cameroon has lately come into my hands, through the kindness of Prof. Pechnel-Loesche. The sender, Mr. Edward Tëusz, gave the following information concerning it. The animal to which it belonged was caught in Kriegschiff Bay, after very heavy rains, and was being devoured by sharks. The contents of the stomach consisted of grass, weeds, and mangrove fruits. None of the natives had ever seen the animal before. In preparing the skull, Mr. Edward Tëusz noticed that the nostrils projected above the surface of the forehead.

I am preparing for publication a detailed description of the skull, and must here confine myself to remarking that, though the animal belongs to the genus Sotalia, it differs in several essential points from all the species of that genus hitherto described. I have no doubt that it is a new species. There are twenty-seven teeth on each side in each jaw. Their form, in that they are not pointed, but worn down, indicates, as also do the contents of the stomach, that the animal is herbivorous. It therefore seems certain that it is a fresh-water animal. It is well known that other Sotalia live in rivers.

Jena, June 20. WILLY KÜKENTHAL.

PHYSICAL SCIENCE FOR ARTISTS.[1]

I.

I THINK it right that I should begin by explaining how it is that I am here to-day, to lecture to you on a subject which touches art as well as science. It happens in this wise. Some years ago, while studying a certain branch of optics, it became important for me to try to learn something of the exact sequence of colours at sunrise and sunset; and being, like you, busy all day in a large city, I thought it would not be a bad idea, and that it would save a little time, if I studied pictures representing these phenomena *en attendant* the happy holiday time that I should spend in the country. So I went to the Academy and other picture galleries, and endeavoured to get up the information from pictures which I could not at that time get from Nature herself. I then had, as I have still, such an extreme respect for art and artists that I was perfectly prepared to take the pictures as representing truthfully what I wanted to see. The result, however, brought me face to face with a difficulty that I was not long in finding out. I was driven to the conclusion that artists could be divided into two distinct classes—those who studied Nature and Nature's laws, and gave us most exquisite renderings of this or that, and those who apparently considered themselves far superior to any such confining conditions as would be imposed by any law; and that, unfortunately, made me a little doubtful as to the results.

My friend, and your friend, Dr. Russell, happens to know this little bit of my experience, and hence it doubtless is that he requested me to come down to-day to say a few words to you, his plea being that this College is one of the very few institutions of its kind in the world where there is a studio and a physical laboratory side by side.

That, then, is the reason I am here, and what I want to impress upon you to-day is that the highest art can only be produced by those who associate the study of physical science with the study of art, and that therefore the possible producers of the highest art can only be looked for in such an institution as this if training of any kind has anything to do with it.

---

[1] A Lecture delivered at Bedford College, by J. Norman Lockyer, F.R.S. on June 10, 1891.

I think that the *general* conditions of art training as they exist at present absolutely bar any sufficient knowledge of the laws and conditions of natural phenomena on the part of art students.

The *best* art of the time has always been on a level with the best science of the time, and if it had not happened that the first schools and the first Universities clustered round medical schools and schools of anatomy, I do not think that so much attention would be given to-day to anatomical science to the exclusion of all other branches.

You see, then, it comes to this. It is conceded by the art world that in a certain direction the phenomena of Nature require to be studied, otherwise that tremendously exuberant literature on Anatomy for Artists would not have been written, and more than half of the time of students of art would be spent in studying something else rather than those things which they do study.

It is on that ground that I would venture to say that in other institutions, as in this one, the study of physical science should be added to the other branches already recognized by the art world.

I am not an artist. I am not an art critic. I am almost unacquainted with the language usually employed by those who write on art subjects. I shall not deal with opinions, the algebraical sum of which in relation to the qualities of any one picture I have often noticed is zero; but what I shall try to do is to stick as closely as I can to the region of fact, and endeavour to show you, by two or three individual instances, how a student who wishes to become a great artist—as some of you no doubt do—will find his or her ambition more likely to be realized if the study of physical science be combined with that of "Art as she is taught" to-day.

In looking at the Academy Catalogue this year one finds the motto, "La mission de l'art n'est pas de copier la nature, mais de l'exprimer," and this is a true motto. But let us analyze it a little. To "express" suggests a language; a language suggests a grammar, if it is to be perfect, satisfying. But what can this grammar be, in the case we are considering, but the laws underlying the phenomena the "expression" of which, in his own language, constitutes the life-work of the artist. Should he be content to show himself a bumpkin? Are solecisms to be pardoned in his expressions because, so far, scientific training and thought are so limited? Is he justified in relying upon the ignorance of mankind, and, if so, is the highest art always to remain divorced from the highest knowledge?

Now it so happens that the branch of physical science which is above all things the thing to be studied by artists, is the branch of it which is already familiar to you—namely, optics. There could be no art without light; no artists without light; and the whole work of an artist, from the beginning to the end of his life, is to deal with light. Now we live in a world of white light. We might live in a blue world, or a green world, and then the condition of things would be different; but we can, in our laboratory, make our world red or green for the moment; but sometimes, indeed, when we do not seek to make this experiment, we find the world changed for us by the means which we employ for producing artificial lights, such as candles, gas, or the electric light; since in these, colours are not blended in the same way as in a sunbeam.

We thus come to the question of the radiation of light, and the way in which this light, whatever its quality, is reflected by natural objects; it is by this reflection that we see them. Everything that an artist paints which is white, is painted white by him for the simple reason that it reflects sunlight complete. It is perfectly clear that any reflecting surface can only reflect the light which it receives, although all surfaces do not reflect all of it—we have red walls and green trees; the direction of the light is not changed, except in the way of reflection, and you are already acquainted with the imperative law of optics—that when light falls upon a body and is reflected, the angle of reflection is equal to the angle of incidence.

To us this drastic law is of the very highest interest. We can apply it to art in a great many ways, but I will only take two very simple ones. Oftentimes it is our fortune to be in the country by the side of a river, or at the seaside. In both cases we see things reflected in water, and at first sight it would seem that here the artist ought to find perfectly free scope; but the worst of it is that, though he has free scope, sometimes his picture becomes very unpleasant to people who are acquainted with the law I have stated. I find here some diagrams, prepared by the kindness of some of our friends, which will show you the intimate connection between art and science in this direction. In the pictures which you will see in the Royal Academy and the New Gallery, I fancy you will see some which, if you care to study them from this point of view, will be found not to agree with the law.

In the diagrams we have a surface of water and observers at the top and bottom of a cliff. We have on the other side of this surface of water a tree. Now, what anyone would do who disdains to "copy" Nature, and who paints without thinking, is this: he would paint what he saw on the bank, and then turn it upside down and paint it again. But you see that will not do, because the conditions are as you see them here. The higher spectator, No. 1, the angles of incidence and reflection being equal, although he can see the upper part of the tree and part of the trunk, will not be able to see it all completely reflected in the water. You see that the lower part of the tree cannot be seen in the reflection, because any light reflected by it first to the water and then to the eye is really cut off from the eye of the spectator by the bank; if you greatly vary your distance from the other side of the water, you will find the reflection as represented in the other diagram. Now, to anyone who has studied optics, if such a matter as this is represented wrongly in a picture, it becomes an intolerable nuisance, and when you go away you feel sorry that the artist did not do justice to what he wished to represent. A good example of truth to Nature in this respect is to be seen at the German Exhibition—No. 205—in one of the landscapes, which I saw last night; it is a beautiful instance of careful study, and is absolutely true in this respect. The artist has shown how a mountain side, with high lights upon it, reflected on the surface of a lake, appears very different in the reflection, in consequence of an intervening elevation near the edge of the water. When you have thought out the difference of the appearances on the lake and on the hillside, you will appreciate the truth and skill of the artist enormously.

Another serious fault arising from the neglect of this same law is to be found in very many pictures in which we get the reflection of the sun or moon in water.

Obviously, if the water is disturbed, the reflection upon the water must depend upon the direction of the disturbance. I need not say more than that to you. You will quite understand what I mean; but if you look at the pictures in the Royal Academy this year—Nos. 677, 1071, and 1155—you can see how very admirably this reflection can be rendered; and if you look at 165 and think the conditions out, you will wonder how the artist should trouble to paint something that is absolutely opposed to the physical law.

You know that, in those instances where you get a natural reflection, if the light source be beyond the object which reflects the light, the nearer it is in a line with it the more light will be reflected. You see that that rule relates to almost every landscape or seascape that is painted, for the reason that our air is filled with particles which reflect light. If it were not so, our atmosphere would be absolutely black.

It therefore follows that the light of the sky must increase in intensity as the sun or moon is approached—

that is to say, in a sun-setting or moon-setting, if you paint an unbroken sky, there must be an increase of intensity towards the light source. I am almost ashamed to make such a statement, because it is so obvious to you as students of science, but to the artist who is not a very strict observer, why should it strike him? The fact remains that it has not struck a great many artists. If you study the pictures Nos. 650, 989, 1144, in the Royal Academy, and No. 39 in the New Gallery, you will find there indications of a neglect of this law. Now the sky is far more luminous than it ought to be by the light indicated by the landscape. Again, the setting sun is not so bright as the clouds which it is supposed to illuminate, and in some cases there is absolutely no grazing reflection indicated, and, if anything, the sky is rather less luminous where the sun is than further away!

A good rule, and one which a student of physical science would be certain to act upon with considerable care, would be never to show anything as reflected which was not there.

An interesting example of this kind was exhibited in the Academy some years ago. It so happened that a French man of science wrote a book on physical phenomena, beautifully illustrated. Among the illustrations was a coloured copy of a photograph of a soap bubble. Now the laboratory in the Collège de France, in which the photograph was taken, was, like yours, very well lighted by many windows, and the soap bubble was blown in the middle of it. A translation of this book appeared in English, and the illustrations were reproduced.

An artist had a most excellent idea. He thought he would paint a picture of a garden, which he did admirably. The foreground looked bare, so he thought he would put children playing in it. It next struck him, apparently, that the children did not seem to be quite sufficiently occupied, so he painted one blowing soap bubbles. But, alas! less fortunate than you, the artist had no laboratory in which he could blow and study soap bubbles for himself; so what did he do? He copied the bubble which was riddled with windows, although there were no windows in the garden. He thought that the nature of bubbles was windowy.

Then, again, in the matter of reflection, it would not be right that I should fail to remind you that, besides things terrestrial, we have the moon, which rules the night, and rules the night because it reflects the sunlight to us. Now, in a little talk like this I must not take up much time with astronomy, but it is fortunate that books on astronomy can be got for 6*d.* or 1*s.* which will tell us, say, in half an hour, the chief points about the moon which we need consider in the present connection. The moon is lighted by the sun. The sun can only light one half at a time. If we are on the side of the moon which is lighted by the sun, we must see the complete lighted half which we call a full moon. If we see a full moon, we must have our back to the sun. When the position of the moon with reference to the earth is such that we can see half the lighted portion of the moon, we generally find that the part of the moon which is turned to the sun is lighted up.

But none of these things are so in art. Last year a picture in the Academy was absolutely disfigured by the dark part of the moon being turned to the sun. Surely it was not worth the artist's while to paint a moon if he did not know how to do it. But the moon has been treated, if possible, worse than that. Some years ago a friend who knew I was interested in astronomy had another friend who had painted a picture, and he wished me to look at it to see if the moon was right. I went and saw the picture, and had to say that the moon was wrong. It was perfectly clear that the picture was intended to represent the sun setting on the right, beyond the part of the landscape included in the picture, so that the moon rising on the left, and shown in the picture, must be full. My friend said to me he knew this, and that as a matter of fact the artist had painted a full moon to start with, but he had altered it because it "destroyed the balance of his picture." That you see was where art came in. And then he added that the painter was not satisfied with the moon as it stood! I told my friend to say that I regretted that the full moon destroyed the balance of the picture, and that even a delicate crescent did not make things quite right, and I suggested that the effect of two or even three moons, of different sizes if needs be, should be tried. The artist said that this was nonsense; I replied that I did not consider it greater nonsense than the moon as he had represented it, and so the matter ended.

I am sure that the students of this College will know that such things as these are to be avoided, even if there were difficulties caused by the non-existence of a book on astronomy. No artist need paint a moon in a picture if he be too ignorant to paint it properly.

Everything that you paint in a picture, which you paint because it reflects light, should be painted its proper size in relation to the other objects. It seems, however, that the moment a body which reflects light does not happen to be on the surface of the earth, you may, in art, make it as large as you please. I do not think that the moon's distance from the earth gives us any right to treat it in this way.

An eminent American astronomer some years ago looked at the pictures in the New York galleries from this point of view. The moon subtends a certain angle. Everything else in a picture can be expressed in this way the moment you put a moon into it. This astronomer took the trouble to get out a statistical table of the heights of the different mountains and hills as drawn by American artists in pictures of places taken from other places (the distances being therefore known) with a moon thrown in. The maximum height was 105 miles, and the lowest 13!

Next, permit me to say a few words on another point, in order to show that the student of art will delight more and more in his work as he or she knows more and more of physical science. I now take refraction. You know that refraction can be divided into deviation and dispersion. The phenomena of deviation teach us that when a beam of light, whatever its colour, passes out of one medium into another its course is changed. An experiment, which is easily performed and which is more a home experiment than a laboratory one, is to put a coin into a basin and look over the edge in such a direction that the coin is just invisible: then fill it with water, the coin appears. Another experiment is to insert a straight body, such as a pencil, into this bowl of water: it appears to be broken; refraction, then, appears to make water shallower than it really is. If you look at 1094, you will find that this deviation has been made to act the wrong way.

It is rather a bad thing to attempt to paint a nymph partly in and partly out of *clear* water, because her body, if the picture be truly painted, would follow suit with the pencil.

Passing from deviation to dispersion we come to rainbows. You have learned, and perhaps seen demonstrated by experiment, that we deal with a beam of white light coming from the sun and refracted at the front surface of a rain-drop. It is next reflected and again refracted down to the eye, so that the eye sees a bow, with all the spectrum colours due to the dispersion. If the light be strong enough, we get what is called a supplementary bow, and, in consequence of internal reflections, the two reds are brought together.

The point is that in this dispersion, brought about by the rain-drops, the effect is produced in a plane passing through the sun, your eye, and the rain-drop; your eye being in the centre, so that if you see a rainbow at all, you must have your back to the sun. The bow is always circular, and high or low according to the height of the sun. Those are, of course, conclusions which a very restricted study of physical science will make perfectly clear: why you get the two reds together when two bows are visible; why the blue is inside, and the red outside the single bow, also follows from a demonstration which your teacher will give you, or which you can get from a book. The main point is that a rainbow is produced by a physical cause; so that, if you once grasp the idea of the cause of a rainbow, its whole anatomy will remain for ever with you.

It is quite impossible for you to see a rainbow in prospective, or projected on the sky as an ellipse. That will be quite clear, I think. Still, both these are recognized art-objects. I am sorry to say that in this year's Academy there is one case in which you will find that the fundamental condition of having your back to the sun has been neglected or forgotten by the artist. In No. 395 a most exquisite stump of rainbow is seen, most beautifully painted, and you naturally think, of course, that you have your back to the sun, but the artist has not been contented with painting the rainbow, he has painted cattle as well, and their shadows sweep across the picture. Another rainbow, 595, is excellently painted. The artist not only knows a great deal about rainbows, but wishes you to know that he knows, an umbrella being emphatically *en évidence*.

(*To be continued.*)

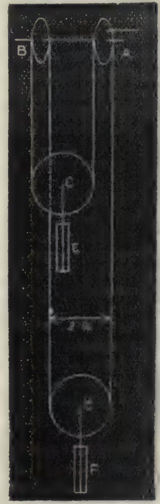
THE FARADAY CENTENARY.

On Wednesday, June 17, at the Royal Institution, Lord Rayleigh delivered a lecture in connection with the hundredth anniversary of Faraday's birth. The Prince of Wales presided.

Lord Rayleigh said that the man whose name and work they were celebrating was identified in a remarkable degree with the history of that Institution. If they could not take credit for his birth, in other respects they could hardly claim too much. During a connection of fifty-four years, Faraday found there his opportunity, and for a large part of the time his home. The simple story of his life must be known to most who heard him. Fired by contact with the genius of Davy, he volunteered his services in the laboratory of the Institution. Davy, struck with the enthusiasm of the youth, gave him the desired opportunity, and, as had been said, secured in Faraday not the least of his discoveries. The early promise was indeed amply fulfilled, and for a long period of years by his discoveries in chemistry and electricity Faraday maintained the renown of the Royal Institution and the honour of England in the eye of the civilized world. He should not attempt in the time at his disposal to trace in any detail the steps of that wonderful career. The task had already been performed by able hands. In their own Proceedings they had a vivid sketch from the pen of one whose absence that day was a matter of lively regret. Dr. Tyndall was a personal friend, had seen Faraday at work, had enjoyed opportunities of watching the action of his mind in face of a new idea. All that he could aim at was to recall, in a fragmentary manner, some of Faraday's great achievements, and if possible to estimate the position they held in contemporary science.

Whether they had regard to fundamental scientific import, or to practical results, the first place must undoubtedly be assigned to the great discovery of the induction of electrical currents. He proposed first to show the experiment in something like its original form, and then to pass on to some variations, with illustrations from the behaviour of a model, whose mechanical properties were analogous. He was afraid that these elementary experiments would tax the patience of many who heard him, but it was one of the difficulties of his task that Faraday's discoveries were so fundamental as to have become familiar to all serious students of physics.

The first experiment required them to establish in one coil of copper wire an electric current by completing the communication with a suitable battery; that was called the primary circuit, and Faraday's discovery was this: That at the moment of the starting or stopping of the primary current, then, in a neighbouring circuit, in the ordinary sense of the words, completely detached, there was a tendency to induce a current. He had said that those two circuits were perfectly distinct, and they were distinct in the sense that there was no conducting communication between them, but, of course, the importance of the experiment resided in this—that it proved that in some sense the circuits were not distinct; that an electric current circulating in one does produce an effect in the other, which is propagated across a perfectly blank space occupied by air, and which might equally well have been occupied by vacuum. It might appear that that was a very simple and easy experiment, and of course it was so in a modern laboratory, but it was otherwise at the time when Faraday first made it. With all his skill, Faraday did not light upon truth without delay and difficulty. One of Faraday's biographers thus wrote:—"In December 1824, he had attempted to obtain an electric current by means of a magnet, and on three occasions he had made elaborate and unsuccessful attempts to produce a current in one wire by means of a current in another wire, or by a magnet. He still persevered, and on August 29, 1831—that is to say, nearly seven years after his first attempts—he obtained the first evidence that an electric current induced another in a different circuit. On September 23rd, he writes to a friend, R. Phillips: I am busy just now again with electro-magnetism, and think I have got hold of a good thing, but cannot say; it may be a weed instead of a fish that, after all my labour, I at last haul up." We now know that it was a very big fish indeed. Lord Rayleigh proceeded to say that he now proposed to illustrate the mechanics of the question of the induced current by means of a model (see figure), the first idea of which was due to Maxwell. The one actually employed was a combination known as Huygens's gear, invented by him in connection with the winding of clocks. Two similar pulleys, A, B, turn upon a piece of round steel fixed horizontally. Over these is



hung an endless chord, and the two bights carry similar pendant pulleys, C, D, from which again hang weights, E, F. The weight of the cord being negligible, the system is devoid of potential energy; that is, it will balance, whatever may be the vertical distance between C and D. Since either pulley, A, B, may turn independently of the other, the system is capable of two independent motions. If A, B turn in the same direction and with the same velocity one of the pendant pulleys, C, D, rises, and the other falls. If, on the other hand, the motions of A, B are equal and opposite, the axes of the pendant pulleys and the attached weights remain at rest. In the electrical analogue the rotatory velocity of A corresponds to a current in a primary circuit, that of B to a current in a secondary. If, when all is at rest, the rotation of A be suddenly started, by force applied at the handle or otherwise, the inertia of the masses E, F opposes their sudden movement, and the consequence is that the pulley B turns *backwards*, *i. e.* in the opposite direction to the rotation imposed upon A. This is the current induced in a secondary circuit when an electromotive force begins to act in the primary. In like manner, if A, having been for some time in uniform movement, suddenly stops, B enters into motion in the direction of the former movement of A. This is the secondary current on the break of the current in the primary circuit. It might perhaps be supposed by some that the model was a kind of trick. Nothing could be further from the truth. The analogy of the two things was absolutely essential. So far was this the case that precisely the same argument and precisely the same mathematical equations proved that the model and the electric currents behaved in the way in which they had seen them behave in the experiment. That might be considered to be a considerable triumph of the modern dynamical method of including under the same head phenomena the details of which might be so different as in this case. If they had a current which alternately stopped and started, and so on, for any length of time, they, as it were, produced in a permanent manner some of the phenomena of electrical induction. The particular apparatus by which he proposed to illustrate those effects of the alternating current was devised by a skilful American electrician, Prof. Elihu Thomson, and he had no doubt it would be new to many. The alternating current was led into the electro-magnet by a suitable lead; if another electric circuit, to be called the secondary circuit, was held in the neighbourhood of the first, currents would be induced and might be made manifest by suitable means. Such a secondary circuit he held in his hand, and it was connected with a small electric glow lamp. If a current of sufficient intensity were induced in that secondary circuit it would pass through the lamp, which would be rendered incandescent. [Illustrating.] It was perfectly clear there was no conjuring there; the incandescent lamp brightened up. One of the first questions which presented itself was, what would be the effect of putting something between? Experimenting with a glass plate, he showed there was no effect, but when they tried a copper plate the lamp went completely out, showing that the copper plate was an absolute screen to the effect, whatever it might be. Experiments of that kind, of course in a much less developed and striking form, were made by Faraday himself, and must be reckoned amongst some of his greatest discoveries.

Before going further, he might remark on what strong evidence they got in that way of the fact that the propagation of the electric energy which, having its source in the dynamo downstairs, eventually illuminated that little lamp, was not merely along the wires, but was capable of bridging over and passing across a space free from all conducting material, and which might be air, glass, or, equally well, vacuum. Another kindred effect of a striking nature, devised by Prof. Elihu Thomson, consisted in the repulsive action which occurred between the primary current circulating around a magnet and the current induced in a single hoop of aluminium wire. Illustrating this by experiment, he showed that the repulsion was so strong as to throw the hoop up a considerable height. Those effects were commonly described as dependent upon the mutual induction between two distinct circuits, one being that primarily excited by a battery or other source of electricity, while the other occurred in a detached circuit. Many surprising effects, however, depended on the reactions which took place at different parts of the same circuit. One of these he illustrated by the decomposition of water under the influence of a single Daniell cell with the aid of self-induction.

About the time that the experiments of which he had been speaking were made, Faraday evidently felt uneasiness as to the soundness of the views about electricity held by his contemporaries, and to some extent shared by himself, and he made elaborate experiments to remove all doubt from his mind. He re-proved the complete identity of the electricity of lightning and of the electricity of the voltaic cell. He was evidently in terror of being misled by words which might convey a meaning beyond that which facts justified. Much use was made of the term "poles" of the galvanic battery. Faraday was afraid of the meaning which might be attached to the word "pole," and he introduced a word since generally substituted, "electrode," which meant nothing more than the way or path by which the electricity was led in. "Electric fluid" was a term which Faraday considered dangerous, as meaning more than they really knew about the nature of electricity, and as was remarked by Maxwell, Faraday succeeded in banishing the term "electric fluid" to the region of newspaper paragraphs

Diamagnetism was a subject upon which Faraday worked, but it would take him too long to go into that subject, though he must say a word or two. Faraday found that whereas a ball of iron or nickel or cobalt, when placed near a magnet or combination of magnets, would be attracted to the place where the magnetic force was the greatest, the contrary occurred if for the iron was substituted a corresponding mass of bismuth or of many other substances. The experiments in diamagnetism were of a microscopic character, but he would like to illustrate one position of Faraday's, developed years afterwards by Sir Wm. Thomson, and demonstrated by him in many beautiful experiments, only one of which he now proposed to bring before them. Supposing they had two magnetic poles, a north pole and a south pole, with an iton ball between them, free to move along a horizontal line perpendicular to that joining the poles, then, according to the rule he had stated, the iron ball would seek an intermediate position, the place at which the magnetic force was the greatest. Consequently, if the iron ball be given such a position, they would find it tended with considerable force to a central position of equilibrium; but if, instead of using opposite poles, they used, *e.g.*, two north poles, they would find that the iron ball did not tend to the central position, because that was not the position in which the magnetic force was the greatest. At that position there was no magnetic force, for the one pole completely neutralized the action of the other. The greatest force would be a little way out, and that, according to Faraday's observations, systematized and expressed in the form of mathematical law by Sir Wm. Thomson, was where the ball would go. [This was illustrated by experiment.]

The next discovery of Faraday to which he proposed to call attention was one of immense significance from a scientific point of view, the consequences of which were not even yet fully understood or developed. He referred to the magnetization of a ray of light, or what was called in more usual parlance the rotation of the plane of polarization under the action of magnetic force. It would be hopeless to attempt to explain all the preliminaries of the experiment to those who had not given some attention to those subjects before, and he could only attempt it in general terms. It would be known to most of them that the vibrations which constituted light were executed in a direction perpendicular to that of the ray of light. By experiment he showed that the polarization which was suitable to pass the first obstacle was not suitable to pass the second, but if by means of any mechanism they were able, after the light had passed the first obstacle, to turn round the vibration, they would then give it an opportunity of passing the second obstacle. That was what was involved in Faraday's discovery. [Experiment.] As he had said, the full significance of the experiment was not yet realized. A large step towards realizing it, however, was contained in the observation of Sir William Thomson, that the rotation of the plane of polarization proved that something in the nature of rotation must be going on within the medium when subjected to the magnetizing force, but the precise nature of the rotation was a matter for further speculation, and perhaps might not be known for some time to come.

When first considering what to bring before them he thought, perhaps, he might include some of Faraday's acoustical experiments, which were of great interest, though they did not attract so much attention as his fundamental electrical discoveries. He would only allude to one point which, as far as he knew, had never been noticed, but which Faraday recorded in his acoustical papers. "If during a strong steady wind, a smooth flat sandy shore, with enough water on it, either from the receding tide or from the shingle above, to cover it thoroughly, but not to form waves, be observed in a place where the wind is not broken by pits or stones, stationary undulations will be seen over the whole of the wet surface. . . . . These are not waves of the ordinary kind, they are (and this is the remarkable point) accurately parallel to the course of the wind." When he first read that statement, many years ago, he was a little doubtful as to whether to accept the apparent meaning of Faraday's words. He knew of no suggestion of an explanation of the possibility of waves of that kind being generated under the action of the wind, and it was, therefore, with some curiosity that two or three years ago, at a French watering-place, he went out at low tide, on a suitable day when there was a good breeze blowing, to see if he could observe anything of the waves described by Faraday. For some time he failed absolutely to observe the phenomenon, but after a while he was perfectly well able to recognize it. He mentioned that as an example of Faraday's extraordinary powers of observation, and even now he doubted whether anybody but himself and Faraday had ever seen that phenomenon.

Many matters of minor theoretic interest were dealt with by Faraday, and reprinted by him in his collected works. He was reminded of one the other day by a lamentable accident which occurred owing to the breaking of a paraffin lamp. Faraday called attention to the fact, though he did not suppose he was the first to notice it, that, by a preliminary preparation of the lungs by a number of deep inspirations and expirations, it was possible so to aërate the blood as to allow of holding the breath for a much longer period than without such a preparation would be possible. He remembered some years ago trying the experiment, and running up from the drawing-room to the nursery of a large house without drawing any breath. That was obviously of great practical importance, as Faraday pointed out, in the case of danger from suffocation by fire, and he thought that possibly the accident to which he alluded might have been spared had the knowledge of the fact to which Faraday drew attention been more generally diffused.

The question had often been discussed as to what would have been the effect upon Faraday's career of discovery had he been subjected in early life to mathematical training. The first thing that occurred to him about that, after reading Faraday's works, was that one would not wish him to be anything different from what he was. If the question must be discussed, he supposed they would have to admit that he would have been saved much wasted labour, and would have been better *en rapport* with his scientific contemporaries if he had had elementary mathematical instruction. But mathematical training and mathematical capacity were two different things, and it did not at all follow that Faraday had not a mathematical mind. Indeed, some of the highest authorities (and there could be no higher authority on the subject than Maxwell) had held that his mind was essentially mathematical in its qualities, although they must admit it was not developed in a mathematical direction. With these words of Maxwell he would conclude: "The way in which Faraday made use of his idea of lines of force in co-ordinating the phenomena of electric induction shows him to have been a mathematician of high order, and one from whom the mathematicians of the future may derive valuable and fertile methods."

THE ROYAL NAVAL EXHIBITION.

THE Naval Exhibition, now being held at Chelsea, is distinctly a popular show. The management—recognizing that the first duty of an Exhibition is not to show a pecuniary deficit—has wisely decided to follow the lead given by Sir Philip Cunliffe Owen, and has devoted the chief of its energies to fireworks, waxworks, peep-shows, pictures, shooting-galleries, mimic sham fights, and musical entertainments of a kind known to sailors as "sing-songs." The end justifies the means. Not only does the Committee of distinguished Admirals labour to supply Londoners with a cheap and innocent means of enjoyment, but the final result will be the establishment of a substantial fund to endow a most deserving charity. Fortuitously there are features which possess a more serious interest; and though there may be nothing especially new in the Exhibition, the man of science who has not been brought much in contact with naval matters may find there a good deal that is worth consideration.

The Exhibition appears to be divided into about half-a-dozen sections, each under the direction of a committee. Of these the "Entertainments" and "Refreshments" Committees are of course the chief; but the Models Committee appears to be the one which has made the most serious effort to present a distinctly naval subject in logical sequence. In the Seppings Gallery there is a collection of models of warships illustrating the progress of naval architecture, from the *Great Harry* down to the very latest design of armour-clad battleship. The model of the *Great Harry* is of very doubtful authenticity, and is of modern construction, having been made by the aid of such pictures of the great sixteenth-century ship as exist. No historical collection of British warships would, however, be even approximately complete without a representation of this vessel. Charnock, our great authority on the subject, has styled her "the parent of the British Navy"; and if it be true, as supposed, that she was the first warship to sail on a wind, the claim is most amply justified. In fact, naval architecture as a science was not founded until it was discovered that ships could be, otherwise than by the aid of oars, taken to the quarter from which the wind was blowing. It must have seemed a great feat in those days—little less than necromancy. Fortunately for the timid intellects of our ancestors, the revelation broke upon them gently, for the rounded hulls, high topsides, and curiously rigged craft could not have sailed more than a point or two to windward. Still, it was the *Great Harry*, or one of her contemporaries, by means of which this new feature in seamanship was inaugurated; a feature by which the great middle period in the world's history of naval warfare was created, and which enabled the sailors of those times to make a distinct advance upon the lessons taught them by their instructors in the art of shipcraft, the Phœnicians, Romans, and Scandinavians. It would have been well if we had improved on our predecessors in other nautical matters as well; and we then should not have had, even in the present century, our shipwrights attaching lead sheathing to ships' bottoms with iron nails. The Romans used copper fastenings when they lead-covered the under-water part of their vessels.

There are but three models of seventeenth-century ships in the Exhibition, but one of these is a vessel that forcibly illustrates, by contrast, the mutability of the present age. The *Royal William* was designed by the first great naval architect, Phineas Pett—whose name might almost more appropriately have been given to the Models Gallery than that of Seppings—and was built at Chatham in 1670. She was originally a three-decker, carrying one hundred guns, but in 1757 she was cut down to a ship of 84 guns, and was finally broken up in 1813—a fact duly recorded by the present Director of Naval Construction, Mr. W. H. White, in his delightful lecture on "Modern War Ships," delivered a few years ago at the Mansion House. The *Royal William* must not, however, be taken as an example of the endurance of ancient materials so much as of the slow changes in design which characterized the proceedings of our ancestors. The original material part of the *Royal William* only lasted twenty-two years, for she was rebuilt, we are told, in 1692, and again in 1719; so that in this respect she compares unfavourably with so modern a vessel as our first ironclad, the *Warrior*, which has only recently been taken out of the Navy after a service career of not far from 30 years. Even now the *Warrior* has not been removed from the Navy list because she has become worn out, but simply because she has become obsolete. If we could reach finality in design—if the inventive brain would stagnate—there is no reason why the modern iron-built warship should not outlast its wooden predecessor by almost as great an extent as it exceeds it in power of destruction. It is true the natural life of the old ships was a long one. The *Victory* was forty years old when she was engaged in the battle of Trafalgar, and had seen much active service, having been launched at Chatham in 1765; but then she had been laid by as worn out in 1801, and it was only after extensive repairs that she was made fit for sea. A year or two ago, it will be remembered, she was found to be so rotten that she would have sunk at her moorings had she not been taken into dock and in part rebuilt. On the other hand, there is no reason why an iron ship should not last, provided she were properly painted and kept up, perhaps until the era when warships will have become relics of a barbarous past. The expression "properly painted" must be here taken in its literal sense; and with regard to steel ships due steps must be followed to remove mill-scale, a precaution which has not always been taken of late, as quite recent mishaps have testified.

Passing from hulls to motive power, we find the same governing principles as to durability of material and impermanence of design more strongly emphasized in the practice of to-day compared with that of the naval era which closed with the introduction of steam and iron hulls. With comparatively small variations in detail the rig of war ships has remained unchanged from the days of Pett down to those within the memory of men still living. The *Henri Grace à Dieu* shows a distinctly mediæval rig—although her fighting-tops are ridiculously like those of our very latest armour-clads—but it would take almost a sailor's eye to point out the differences in sail plan between Vandevelde's beautiful painting of the *Sovereign of the Seas*, "built in 1637," and the ships which appear on the canvases of Stanfield, Turner, and Cooke. So much for permanence of design with masts and sails; with the succeeding mode of propulsion, engines and boilers, we find as striking a result in the opposite direction. Steam machinery was first introduced into the Royal Navy in small gun-boats, and later in the paddle-wheel frigates, but it was not until the screw was proved to be the more effective instrument that even the most sanguine engineers could hope that engines and boilers would successfully rival masts and sails as a means of propulsion. We pass over, therefore, the unimportant era of paddle-wheels, but even taking screw engines alone we find that during the last forty years far greater changes have taken place in the design of steam machinery than characterized the arrangement of masts and sails during the two hundred years elapsing between the time the *Sovereign of the Seas* was built and the practical introduction of steam into the Navy; indeed we might, without any great fear of contradiction, go further and say that to the eye of the engineer there is no greater affinity between the screw engines of forty years ago and those of the present day, than existed between the rigging of the ships of the Norse sea-kings and those of almost our own day, putting on one side only the element of size. The collection of engine models in the Exhibition is far from complete, and is not to be compared with that of ship models. There is a good reason for this, as engineers work to drawings, and models are seldom made excepting as records; whilst their cost is so great as to render them available only for very rich firms. The collection of models shown by Messrs. Maudslay, Sons, and Field constitute the greater part of the historical collection in the Exhibition. Here may be seen representations of the first types of steam-engine introduced into the Navy; and we think a comparison of the early engines in this collection with, say, the magnificent model of the *Sardegna's* engines, shown by Messrs. Hawthorn, Leslie, and Co., will bear out the remarks we have made. What path the progress of marine engineering will follow in future it is difficult to forecast. The inventions of to-day always seem to have reached finality, but it is difficult to imagine that any fundamental change can be effected so long as we retain the use of steam as a vehicle for the conversion of heat into work. It may be that a little engine shown in the Exhibition—Priestman's oil engine—may contain the germ of a principle upon which marine engines may be designed in future, and that before we have got far into the twentieth century the marine boiler, with all its costliness and complication, may have become as much a relic of the past as the pole masts and uncouth sails of the *Great Harry*. Before that time arrives, however, the four-stroke cycle will have to be superseded.

It is, however, the steam boiler, rather than the engine, which has governed the design of ship machinery. Forty- to forty-five years ago, steam pressures were not generally higher than 5 to 8 pounds per square inch. With the introduction of tubes in place of flues, which took place between 1840 and 1850, the working pressure rose to 15 pounds per square inch. The square box boiler was in use, and with that type the working pressure was limited to about 30 pounds per square inch, or not much beyond, unless the staying of the flat surfaces was carried to an undesirable extent. With such a limit of pressure, the simple expansion engine was, properly, the usual type, but when the cylindrical marine boiler was introduced, the average steam pressure quickly rose to 60 pounds to the square inch, and the compound engine naturally followed. The surface condenser formed a necessary part of this step in advance, for, with the higher temperature due to the increased steam pressure, it was impossible to pass large quantities of salt water through the boilers without rapidly scaling them up. For some time the difficulty in generating higher pressure steam caused stagnation in marine engineering practice; until the substitution of steel for iron in boiler making, the advent of new types of furnaces, and improvements in the machinery used in boiler construction have enabled pressures as high as from 150 pounds to even 200 pounds to the square inch to be carried. The result has been that, for the two-cylinder compound engine, there have been substituted two types of engine, known respectively as the triple expansion engine and the quadruple expansion engine. The names are misleading, as even the ordinary compound engine expands its steam more than three or four times.

The growth of the science of marine engine design, which we have so briefly sketched out, may appear, to those who are not engineers, but little more than a record of increasing steam pressures. Undoubtedly a higher steam pressure has been the fundamental reason for these advances, but the carrying out of these successive changes in pressure has necessitated an entire reconstruction of marine engine practice; so that an engine working at 15 pounds pressure can hardly be said to belong to the same category as one working at 150 to 200 pounds pressure. Tooth-wheel gearing, which was first used with screw propellers, has long ago disappeared, side levers and trunks are no longer introduced, and the surface condenser has become a necessity. In the old days, with jet condensers, the boilers were fed entirely with salt water, now in the best marine practice the condensed steam is all returned to the boiler, excepting that which is unavoidably lost, and this quantity is made up by special distillers and condensers, the manufacture of which has introduced a new branch of marine engineering, as may be judged by several exhibits by different firms in the Exhibition. The practice of circulation of refrigerating water through the surface condenser by means of separate centrifugal pumping engines has also introduced a distinctive type of auxiliary marine engine, upon which several important firms have been chiefly employed. Indeed, the increase in auxiliary machinery has been as marked a feature in the recent progress of marine engineering as have been the changes in the main engines themselves. A battleship of the first class will carry between seventy and eighty separate engines, in addition to those used for driving the propellers. These include electric light engines, hydraulic machinery in connection with the working of heavy guns, steering engines, &c. As an instance of what is gained by the use of auxiliary machinery, an instance given by Mr. White may be quoted. On one occasion it took 78 men 1½ minutes to put the helm of the *Minotaur* hard over. Steam gear was subsequently fitted, by the aid of which two men were able to do the same thing in 16 seconds.

We do not propose to give a list of the various objects exhibited, to which we have referred in penning these remarks. The official catalogue performs that function far more completely than we could hope to do. The collection at Chelsea is well selected and fairly complete, and there will be found there material for object-lessons in all we have advanced in this brief sketch. We may, however, with advantage, add a few figures as to money cost, which cannot fail to be of interest, and for which we are indebted to the Director of Naval Construction. The cost of a 100-gun line-of-battle ship at the beginning of the century was about £65,000 to £70,000, armament and stores being excluded. The corresponding outlay on the 110-gun sailing three-deckers of 1840 was about £110,000; and that of the 121-gun screw three-deckers of 1859 about £230,000, machinery included. The *Warrior*, completed in 1861, cost over £375,000; and the *Minotaur* class about £480,000. With the increase in size of the *Dreadnought*, and the introduction of hydraulic mechanism, came an increase of cost to £620,000; while the *Inflexible* cost no less than £810,000." The *Nile* and *Trafalgar*, complete with armament, would represent little less than a million sterling each. The cost of the armour-plating, propelling machinery, and hydraulic gun mountings alone, would have paid for five first-rates of Nelson's time. The sum paid for the armour alone on one of our latest battleships, such as the *Royal Sovereign*, would pay for the Natural History Museum at South Kensington; whilst even a first-class torpedo-boat costs as much to build and equip as a 40-gun frigate of Nelson's time.

A GEOLOGICAL EXCURSION IN AMERICA.

I BEG to call to your attention the following short account of a geological excursion planned for the benefit of foreign geologists who may attend the coming meeting of the International Geological Congress in this city in August next. It will afford an exceptionally favourable opportunity for European geologists to become personally familiar with the most important geological phenomena of the United States.

I venture, therefore, in their interest, to request that you publish some notice of it in your widely circulated periodical, with a request that those who desire to take part in it will kindly advise me as early as possible, in order that arrangements may be thoroughly perfected beforehand. A single train will carry 75 to 100 persons comfortably. If more join, the party will be arranged in two trains. Arrangements will have to be made beforehand at the various stopping places along the road for the reception of the party, and you can therefore readily understand the importance of knowing as early as possible how many are to be accommodated.

S. F. EMMONS, Secretary.

Washington, D.C., May 30.

For the close of the fifth session of the International Congress of Geologists, which is to be held at Washington, D.C., from August 26 to September 2, a grand geological excursion has been organized, which presents unusual attractions and facilities for the European geologists who attend the Congress, and who wish to see some of the geological wonders which have become familiar to them through the memoirs of American geologists. The excursionists will start from Washington, on September 3, on a special train of Pullman vestibuled cars, which will constitute a moving hotel, being provided with sleeping and toilet accommodations for both ladies and gentlemen, restaurant cars, smoking, reading, and bath rooms, and barber's shop, and so arranged that travellers can pass freely at all times from car to car through covered passages. It will accompany the party wherever the rails are laid in the regions visited, the hours being arranged so that all the most interesting portions of the route will be passed over in the daytime, and stops may be made wherever any object of special interest to the travellers presents itself. American geologists who have made special studies of the different regions visited will accompany the train, and explain their geological structure upon the ground. The main route laid out is over 6000 miles (nearly 10,000 kilometres) in length, and extends over 38° of longitude and 12° of latitude. It is planned to occupy 25 days, and the cost per person will be 265 dollars (1325 francs), which will cover all necessary expenses, of whatever kind, during the trip.

The following are the principal objects of geological interest which will be seen by those who make the excursion:—

Going westward, the Appalachian Mountains are first crossed, and an opportunity will be had to see the closely appressed Palæozoic rocks which constitute their typical structure. The prairie region of Indiana and Illinois, at the southern end of Lake Michigan, its ancient outlet into the Mississippi River, will be seen on the second day, and the Kettle moraines of the ancient Glacial sheet will be visited under the guidance of Prof. Chamberlin. On the third day the twin cities of Minneapolis and St. Paul, centres of the great wheat-growing region of the north-west, will be visited, and glacialists will have an opportunity to see one of the time gauges of the Glacial period, at the Falls of St. Anthony, on the Mississippi River.

During the fourth day the Great Plains of Dakota will be crossed, and toward its close the characteristic Badland topography of the Upper Missouri region will be seen. On the morning of the fifth day the travellers will leave the train at the entrance to the Yellowstone Park, and during the following week will be transported by stages through the Park region, stopping at rustic hotels established near points of special interest. The various geyser basins, the hot lakes and mud volcanoes, the obsidian cliffs, the falls and cañon of the Yellowstone River, the Yellowstone Lake, and other objects of interest, will be successively visited under the guidance of Messrs. Arnold Hague and Jos. P. Iddings.

On the twelfth day the railroad journey will be resumed, and, after crossing the crest of the Rocky Mountains in Montana, a stop of several hours will be made at the famous mining town of Butte, whose mines produced, during 1890, over 26 million dollars worth of copper, silver, and gold.

The morning of the thirteenth day will find the travellers on the edge of the great lava plains of the Snake River. Those especially interested in volcanic phenomena will have an opportunity here of making a side trip across these plains to Shoshone Falls, where the Snake river makes a single leap of over 200 feet, and cuts a narrow gorge 600 feet deep in the andesitic and basaltic lavas. The main party meanwhile will proceed southward into Utah, viewing the desert mountain ranges, the shore-lines of ancient Lake Bonneville, and skirting the shores of its present relic, the Great Salt Lake, will reach Salt Lake City, the Mormon capital, in the afternoon. A halt of three days will be made in Salt Lake City, which will give the travellers an opportunity of seeing the Mormons, the desert scenery around Salt Lake (with bath in the lake), and the magnificent Wahsatch Mountains. The Pleistocene phenomena will be explained by Mr. G. K. Gilbert, and the mountain structure and mining geology by Mr. S. F. Emmons.

On the sixteenth day the railroad journey will be continued across the Wahsatch Mountains into the plateau region of the Colorado River, crossing that stream in the afternoon, and obtaining views of great monoclinal scarps, and groups of laccolitic mountains in the distance.

On the seventeenth day the Rocky Mountain region of Colorado will be entered, through its finest cañon gorges, affording wonderful geological sections. Halts of a few hours each will be made at Glenwood Springs and at the famous mining town of Leadville, which has produced over 150 million dollars worth of silver and lead.

On the eighteenth day the train will descend the great mountain valley of the Arkansas River, between mountain peaks over 14,000 feet high, and through cañon gorges 3000 feet deep, debouching upon the plains through the Royal Gorge at Cañon City, where a remarkable geological section in the "Hogback" ridges will be visited. A short stop will be made at Pueblo, a great centre of smelting works; and Manitou Springs, in a sheltered nook under Pike's Peak, will be reached in the evening.

The nineteenth day will be spent at Manitou Springs, the vicinity of which abounds in objects of geological and mineralogical interest, and those who wish may make the ascent of Pike's Peak (14,200 feet) by rail.

The twentieth day will be spent at Denver, the capital of Colorado, a beautiful city of 130,000 inhabitants, having a view of the whole eastern front of the Rocky Mountains. For those who desire it, a further excursion of ten days or more will be organized under the guidance of J. W. Powell and C. E. Dutton, to the Great Cañons of the Colorado River in Arizona, which they have so fully described in their writings. More detailed visits to the mining districts of Colorado will be directed by S. F. Emmons for those who wish to remain over for that purpose. Those who remain over will receive tickets securing them passage to New York by regular trains when they are ready to start.

The special train will leave Denver on the evening of September 21, crossing the Great Plains of Kansas and Nebraska and the Mississippi Valley, and reaching Chicago on the evening of the 23rd. A day will be given to Chicago, and thence the train will skirt the Great Lakes, Michigan, Huron, and Erie, crossing a portion of Canada, and reaching Niagara Falls on the morning of September 25. Leaving there in the evening, the travellers will descend the beautiful valley of the Hudson River early the following morning, and reach New York before noon of September 26.

NOTES.

THE Delegates of the University Press have informed Prof. Sylvester that they will be prepared to bear the expense of publishing in quarto a complete edition of his mathematical works. We understand that a memorial recommending this course was addressed to the Delegates of the Press, numerously signed by leading mathematicians of the two English Universities, and by eminent members of the French Academy of Sciences.

GEOLOGISTS on this side of the Atlantic will learn with deep regret that Captain Dutton, whose admirable memoirs in the Reports and Monographs of the U.S. Geological Survey are so widely known and valued, has been ordered to take up military duty in Texas—a wide pastoral region where his genius as a geological explorer will find no scope for exercise. As a member of the Corps of Engineers, he has of course always been liable to be taken away to mere routine service of this kind, for which any ordinary officer of his grade would be sufficient. But the authorities have hitherto appreciated his remarkable powers, and have allowed them free exercise, much to their own credit and greatly for the benefit of science. Whether a new martinet has resolved to apply the rigid rules of the service we do not know. But surely there ought to be public spirit enough in the United States to put such pressure on the Engineer Department as will make it reconsider its arrangements. It has only one Captain Dutton, and should be proud of him and make the most of him.

THE Council of the Royal Meteorological Society has decided to arrange for a general dinner, open to all Fellows and their friends, to be held in commemoration of the entrance of the Society on its new premises. The dinner will take place at the Holborn Restaurant on Tuesday, July 7, at 6.30 p.m.

THE Committee appointed by the Hebdomadal Council, Oxford, to consider in what way the University could assist in the establishment of agricultural education, with a special view to the needs of the County Councils, have now submitted their report. By agricultural education the Committee understand instruction in the sciences, or the branches of science, specially applicable to agriculture, employing the latter term with the larger meaning which must have been present to the mind of Dr. Sibthorp when he designated the professorship founded by him the professorship of "Rural Economy." Used in this sense agriculture becomes not merely the science of the cultivation of the soil, but includes the knowledge of its constitution and properties, of its vegetable products, and of the structure, habits, and uses of the domestic animals that are reared upon it; so that the student has evidently much to gain by a knowledge of such subjects as botany, chemistry, animal physiology, and geology. Taking into account the requirements of the County Councils, the Committee think that the efforts of the University should in the first place be directed to the provision of an adequate supply of persons qualified to be lecturers or teachers; and those members who are most familiar with the wants of the counties lay stress upon the importance of University teachers possessing credentials of practical acquaintance with the details of farming and farm-life, which has hitherto been only accidentally—if at all—acquired by such teachers. Other classes of persons whose circumstances the Committee think deserving of consideration are young men who go to Oxford intending to take an ordinary degree, and then, either as landowners or the agents of landowners, to devote themselves to the pursuit and improvement of agriculture; and young men who might go to Oxford with a view to attending such courses of instruction as would be useful to them in agriculture, but without the intention of taking a degree. Dealing with the means already at the command of the University for providing agricultural education, the Committee point out that the professors to whose services resort would most naturally be had are the following: the Sibthorpian Professor of Rural Economy, the Sherardian Professor of Botany, the Waynflete Professor of Chemistry, the Waynflete Professor of Physiology, and the Professor of Experimental Philosophy (Physics). In addition to these University Professors, there are the Lee's Readers in Chemistry and Physics at Christ Church, and the Millard Lecturer in Physics at Trinity College, whose courses would probably be open to agricultural students. The Committee sketch the proper course of study for each class of students, and express the opinion that for the organization and supervision of the studies pertaining to agricultural education some further provision is needed than at present exists. In the Sibthorpian Professorship of Rural Economy, which is now vacant, they recognize a foundation capable of being rendered the centre of agricultural education within the University; and they strongly recommend that the duties and emoluments of the chair should be revised.

The annual dinner of the Royal Horticultural Society was held on Tuesday evening at the Hôtel Métropole. The chair was taken by Sir Trevor Lawrence, the President. The toast of the evening, "The Royal Horticultural Society," was proposed by Sir James Paget, who spoke of the work in which the Society was engaged as one that ministered to the happiness and welfare of the whole nation. The President responded. The Society is now in a most prosperous condition, and is to be congratulated on the progress it has made under Sir Trevor Lawrence's leadership.

We print elsewhere a report of the lecture delivered by Lord Rayleigh at the Royal Institution last week in connection with the Faraday Centenary. In commemoration of this anniversary the Royal Institution elected as honorary members a number of foreign men of science, several of whom came to London to be presented with the diploma of membership by the Prince of Wales. As the distinction between the Royal Institution and the Royal Society is not always so well understood in foreign countries as it is in England, the Royal Institution can hardly, perhaps, be congratulated on this "new departure." The following is the list of those on whom the honour was conferred:—Edmond Becquerel, Marcellin Berthelot, Alfred Cornu, E. Mascart, Louis Pasteur, Paris; R. W. Bunsen, Heidelberg; H. L. F. von Helmholtz, A. W. von Hofmann, Rudolph Virchow, Berlin; J. P. Cooke, Cambridge, U.S.; J. Dwight Dana, J. Willard Gibbs, Newhaven, U.S.; Simon Newcomb, Washington, U.S.; Stanislas Cannizzaro, Pietro Tacchini, Rome; Julius Thomsen, Copenhagen; T. R. Thalen, Upsala; Demetri Mendeleef, St. Petersburg; J. C. G. de Marignac, Geneva; J. D. van der Waals, Amsterdam; J. Servais Stas, Brussels.

A Commission has been appointed for the reorganization of the Paris Museum of Natural History, and held its first meeting last week under the presidency of the Minister of Public Instruction. The members are MM. Berthelot, Bardoux, Burdeau, Charles Dupuy, Darboux, Frémy, Chauveau, Milne-Edwards, and Liard.

A *conversazione* will be given by the President of the Institution of Electrical Engineers and Mrs. Crookes in the galleries of the Royal Institute of Painters in Water Colours on Monday evening, July 6.

On Monday evening, in the House of Commons, Sir H. Roscoe asked the President of the Board of Trade whether he had decided to grant the application of the Committee of the National Institute of Preventive Medicine to become incorporated under the Companies Act, with the omission of the word "limited" in view of the amended proposals which had been placed before him. Sir M. Hicks-Beach replied as follows:—"The amendment of the proposed memorandum of association referred to by the hon. member (by which it is made clear that the grant of the licence now asked for would not in any way imply approval by the Board of Trade of experiments upon living animals, or of any application to the Home Secretary for a licence for that purpose) is, no doubt, an important change in the proposals of the Institute, and will probably meet the objection stated to the deputation which lately waited upon me. There are, however, one or two other points requiring consideration, but I hope shortly to be able to arrive at a decision on the subject."

Sir Prescott Gardiner Hewett, F.R.S., died on Friday night last at his residence, Chestnut Lodge, Horsham, Sussex. He was born in 1812, and in 1836 was admitted a member of the Royal College of Surgeons, of which he was made President in 1876, in succession to Sir James Paget.

With the approval of the President, the Prince of Wales, the Council of the Society of Arts have awarded the Albert Medal to Sir Frederick Abel, K.C.B., "in recognition of the manner in which he has promoted several important classes of the arts and manufactures, by the application of chemical science, and especially by his researches in the manufacture of iron and of steel; and also in acknowledgment of the great services he has rendered to the State in the provision of improved war material, and as chemist to the War Department."

The Report of the Savilian Professor of Astronomy has been presented to the Board of Visitors of the University Observatory, and we learn from it that the photographic telescope, prepared for taking part in the International Chart of the Heavens, is at length complete. The guiding telescope also is provided with a micrometer sufficient to permit the observation of stars at a considerable distance from the centre of the plate, and the camera end of the telescope is fitted with the apparatus devised by the Astronomer-Royal, and executed by Sir Howard Grubb. The Oxford University Observatory is also provided with two *réseaux*, supplied through Dr. Vogel, of the Potsdam Observatory, and has very recently added to its equipment a measuring machine of great delicacy for the discussion of the plates taken in connection with the international scheme. Altogether the equipment of the Oxford University Observatory appears to be in a very forward state of preparedness, and Prof. Pritchard congratulates himself and the University that this equipment has entailed no unusual appeal to funds, on which there are so many claims, but has been supplied by the bounty of the late Dr. De La Rue, supplemented by strict economy in the management of the Observatory in former years. The astronomical work of the past year has been mainly confined to the discussion of the parallax of stars of the second magnitude, and this work is now on the brink of accomplishment. Seven complete determinations, including that of β Aurigæ, have been made in the year, and but six other stars, the measures of which are complete, await discussion. Prof. Pritchard concludes his Report as usual, by acknowledging the aid he has received from his two assistants. and we are glad to see speaks hopefully of his restoration to complete health.

The President of the French Republic inspected the meteorological instruments at the summit of the Eiffel Tower on June 13, and afterwards visited the Central Meteorological Office, where he witnessed M. Weyer's experiments on the formation of tornadoes, and also inspected the instruments which there register the indications of the meteorological phenomena at the top of the Eiffel Tower.

The French Minister of Public Instruction has appointed Dr. Henry de Varigny, assistant in the Museum of Natural History, to report on the University Extension movement, and has commissioned him to study the question in Edinburgh, London, and Oxford.

The proposed law on Universities is exciting a good deal of discussion in France. Many local jealousies have been aroused in connection with the question. Every town that boasts the possession of a tenth-rate medical school, or of an inadequate scientific faculty, wishes to have a University; and its political representatives have, of course, to do what they can to press its claims. On the other hand, the Government, which would willingly establish five or at most six large Universities, desires if possible, to do away with small and useless institutions.

A scientific expedition which has been organized in Maine is about to spend some time in Labrador. The principal object of the party will be to collect ethnological specimens. They will take with them a phonograph, with which they hope to obtain some materials for the study of the language and songs of the Eskimo.

In drawing up schemes for the appropriation of the funds placed at their disposal under the Local Taxation Act, 1890, for the promotion of technical instruction, the County Councils certainly ought not to overlook the claims of girls' education. With a view of aiding County Councils in this department of their work, the Committee of the National Association for the Promotion of Technical and Secondary Education has submitted to them a careful outline of subjects which are adapted for girls, and included within the scope of the Technical Instruction Acts. It is suggested that in each county a committee of ladies should be appointed to devise and carry out a scheme for the technical education of girls.

The *Sussex Daily News* of June 18 records the birth of a sea lion at the Brighton Aquarium.

On June 18, sixty distinct shocks of earthquake occurred at Serajgunge and Domar, in the Bengal Presidency. Many buildings were slightly damaged. At Serajgunge continuous earthquake shocks had been felt from noon on the preceding day.

According to a telegram from Rome, dated June 22, a strong shock of earthquake was felt that morning at Avigliano and at Aquila.

In his report on the Royal Botanic Gardens, Ceylon, for 1890, Dr. Trimen refers to the kinds of cacao in cultivation there. There is no reason to suppose, he says, that they have under cultivation more than one species of *Theobroma*, but every probability that all the varieties trace their origin to a common wild parent. It would be interesting to know which of the two fairly well-marked races recognized in Ceylon is the nearer to this original type, and the facts could probably be ascertained in Central America. The names "Criollo" and "Forastero" applied to them simply mean "wild and foreign," and seem to have had their origin in Trinidad, but it is doubtful if the former was ever really a native plant there. It was, however, the sort at one time exclusively grown in that island, where, having died out, its place was supplied by the "foreign" sort, no doubt obtained from the mainland. As seen in Ceylon, the "Criollo" (called also there "Caracas" and "Old Ceylon Red Cacao") presents very little variety, but the "Forastero" shows a remarkable range in form, size, and colour of pod and seed. No doubt crossing goes on freely in plantations even between the two main races, and it is well known in Ceylon that seed from a single tree gives a very varied progeny; but a curious remark was recently made to Dr. Trimen by a large grower, who has great opportunities for observation, that the "Forastero" varieties, which he chiefly cultivates, appear to be gradually changing their characters and becoming more like the "Old Ceylon Red," the seeds losing their dark colour on section, and becoming pale or nearly white.

In *Himmel und Erde* for June, Prof. G. Hellmann, of Berlin, begins a series of articles entitled "Meteorologische Volksbücher," being an inquiry into popular and typical meteorological works from the earliest times, and into the nature of their contents. The works to be discussed are more particularly those of Germany, although foreign literature will also find subsidiary consideration. Two works are referred to in the present article:—(1) "The Book of Nature," by Konrad von Megenberg, which is the oldest natural history in the German language, and was written about the year 1350—nearly a century before the invention of printing. It was first printed in 1475, and went through many subsequent editions. Much attention and original thought was given to meteorological subjects, and the author divided the wind-rose into 12 points; but the work is to some extent based upon a still unpublished Latin manuscript by Thomas Cantimpratensis, "Liber de natura rerum," which was written before the middle of the 13th century. (2) "Elucidarius." The author of this work is not known with certainty, but is supposed to be Jakob Köbel. This remarkable work was first published in German, in the year 1470, and was much sought for in most European countries in the 15th and 16th centuries. It deals with a variety of subjects, including meteorology and geography, and many editions were published in various countries. Dr. Hellmann gives copious extracts from the works; and historical research being a subject in which he carries great authority, his treatment of it will be found both interesting and instructive.

Messrs. Vieweg and Son, of Brunswick, intend publishing a German translation of Mr. Denning's new book, "Telescopic Work for Starlight Evenings."

A work entitled "Synopsis der Höheren Mathematik," by J. G. Hagen, Director of the Georgetown College Observatory, Washington, D.C., is to be published by Felix L. Dames, Berlin. The work is the result of labour carried on continuously during twenty years, and is intended to present a general view of the higher mathematics. It will consist of four volumes, the first of which will be issued early in August.

A valuable paper on gum-trees, by Mr. D. McAlpine and Mr. J. R. Remfry, has been reprinted from the Transactions of the Royal Society of Victoria for 1890. There are several illustrative plates, the drawings being principally reproductions of photographs taken by Mr. Remfry. These drawings show that the transverse section of the leaf-stalk of a Eucalypt may reveal a pattern useful in the determination of species.

Messrs. George Philip and Son have issued the first number of the *Blue Peter*, a monthly sailing list and review. It is intended that the new journal shall provide ample information for persons who are about to set out by any one of the principal ocean routes. There will also be articles which may serve to remind ships' officers that "there is substantial profit to be derived from a scientific training."

THE third volume of the *Photographic Recorder* is completed by the June number. The volume is admirably illustrated, and contains a valuable record of all that has been done in connection with photography during the past year.

MESSRS. W. F. BROWN AND CO., Montreal, are printing for the Government of Canada "Contributions to Canadian Palæontology," by J. F. Whiteaves, Palæontologist and Zoologist to the Canadian Survey. Part iii. of vol. i. has just been issued. It deals with the fossils of the Devonian rocks of the Mackenzie River basin.

A NOTE by M. Moissan upon the action of fluorine upon phosphorus trifluoride is communicated to the current number of the *Bulletin de la Société Chimique.* A short time ago M. Moissan described a mode of preparing the gaseous trifluoride of phosphorus. The method consisted in gradually adding phosphorus tribromide to warm zinc fluoride, washing the gas first through water, in which it is sparingly soluble, and afterwards drying by means of pumice moistened with sulphuric acid and collecting over mercury. In order to study the action of free fluorine gas upon phosphorus trifluoride as thus prepared, a special piece of apparatus was devised, constructed entirely of platinum and fluor-spar. It consisted of a platinum tube fifteen centimetres long, closed at each end by transparent plates of fluor-spar, through which the phenomena attending the reaction could be observed. The platinum tube was fitted with three side tubes, two of which were placed opposite each other about the centre of the tube, and served for the admission of the fluorine and phosphorus trifluoride respectively; the third or exit tube was of somewhat wider diameter than the entrance tubes, and was bent so as to serve as a delivery tube over a mercury trough. The whole apparatus was first filled with phosphorus trifluoride, and then the fluorine entrance tube was connected with M. Moissan's now well-known apparatus for the preparation of fluorine. As soon as the fluorine came in contact with the phosphorus trifluoride a yellow flame was produced and intense action occurred, with the production of phosphorus pentafluoride. The flame appears to be a comparatively low temperature one. On collecting the gaseous product over mercury, it was found to consist very largely of phosphorus pentafluoride, readily capable of absorption by water, and a small proportion of unaltered trifluoride which could be absorbed by potash. This reaction of fluorine with trifluoride of phosphorus is thus analogous to the conversion of phosphorus trichloride into pentachloride by the action of gaseous chlorine. An interesting reaction has also been observed by M. Moissan to occur between spongy platinum and these gaseous fluorides of phosphorus. When pentafluoride of phosphorus was passed over spongy platinum gently heated in a platinum tube, a partial decomposition was found to occur, and the issuing gas was admixed with trifluoride, and also with free fluorine. The existence of the latter in the free state was abundantly shown by its action upon crystallized silicon. When, however, the temperature of the tube was raised to dull redness, a volatile compound, containing platinum, phosphorus, and fluorine, was obtained, which was carried forward by the gaseous current and deposited in crystals in the cooler portion of the tube. When this crystalline substance is heated, it melts to a viscous liquid, which decomposes at a bright red heat. Analyses show that it is a fluophosphide of platinum, probably of the composition $2PF_3.PtF_4$, analogous to one of the similar chlorine compounds discovered by Schutzenberger, $2PCl_3.PtCl_4$. M. Moissan expresses the hope that by employing some such dissociating compound as this a purely chemical isolation of fluorine may some day be achieved.

THE additions to the Zoological Society's Gardens during the past week include three Stoats (*Mustela erminea*), European, presented by Mr. J. S. B. Borough; an Ocelot (*Felis pardalis* ♂) from South America, a Red-tailed Buzzard (*Buteo borealis*), a Laughing Gull (*Larus atricilla*) from North America, presented by Sir Henry Blake, K.C.M.G.; a Tawny Eagle (*Aquila nævioides*) from Africa, presented by Mr. K. G. Hay; a Blue-fronted Amazon (*Chrysotis æstiva*) from South America, presented by Mrs. A. G. Mussey; a Grey-breasted Parrakeet (*Bolborhynchus monachus*) from Monte Video, presented by Mr. J. R. George; four Common Quails (*Coturnix communis*), British, presented by Mr. J. C. Gie; two Chinese Geese (*Anser cygnoides*) from China, presented by Captain Creaghe; an Egyptian Gazelle (*Gazella dorcas*) from Egypt, two Abyssinian Guinea Fowls (*Numida ptilorhyncha*) from Abyssinia, two Blossom-headed Parrakeets (*Palæornis cyanocephalus*) from India, a Meyer's Parrot (*Pœocephalus meyeri*) from East Africa, three Tibetan Crossoptilons (*Crossoptilon tibetanum*) from Tibet, a Temminck's Tragopan (*Ceriornis temmincki* ♂) from China, deposited; a Vinaceous Amazon (*Chrysotis vinacea*), from Brazil, purchased; two Heloderms (*Heloderma suspectum*) from Arizona, U.S.A., received in exchange; a Burrhel Wild Sheep (*Ovis burrhel*), two Mule Deer (*Cariacus macrotis* ♂ ♀), a Bennett's Wallaby (*Halmaturus bennetti* ♂), two Impeyan Pheasants (*Lophophorus impeyanus*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

TRANSIT OF MERCURY.—The Government Astronomer at Sydney (Mr. C. Todd, C.M.G.) writes as follows regarding the transit of Mercury:—Good observations of the transit of Mercury were secured at the Observatory, on Sunday the 10th. At the ingress the conditions were extremely favourable, the sun's limb and the planet when projected on the sun's disk being exceedingly well and sharply defined, but at the egress the sun's limb was boiling and the planet was somewhat woolly, rendering it difficult to fix the exact time of internal contact. I observed with the 8-inch equatorial refractor, assisted by Mr. Cooke; and Mr. Sells observed with an 8-inch reflector.

The observations were as follow:—

Observer—C. Todd. Power 125.

INGRESS.—*External Contact.*

	Times.		
	h.	m.	s.
A. About one-third on	9	10	11
Internal Contact.			
B. Contact tangential	9	13	6·5
C. Black drop still clinging to limb	9	13	22·0
D. Rupture of black drop; planet clear of limb	9	13	49·5
EGRESS—Power 80. *Internal Contact.*			
E. Formation of black drop touching limb ...	2	0	14·1
F. Tangential contact	2	0	43·8
External Contact.			
Indentation still visible	2	4	14·8
,, ,, barely noticeable	2	4	25·8
Sun's limb complete	2	4	31·8

Observer—Mr. Sells.

INGRESS.—*Internal Contact.*

	h.	m.	s.
a. Planet nearly on disk, but not quite ...	9	12	51·3
b. True contact, momentarily seen	9	13	13·2
c. Planet pear-shaped; point of pear touching sun's limb	9	13	50·7
EGRESS.—*Internal Contact.*			
a. Pear-shaped contact	2	0	34·6
b. True contact	2	1	28·6
External Contact.			
c. Last seen; or sun's limb judged to be complete...	2	4	48·6

OBSERVATIONS OF TELLURIC LINES.—The May number of the *Memorie della Società degli Spettroscopisti Italiani* contains a paper by G. B. Rizzo on the telluric lines in the solar spectrum. Signor Rizzo has compared the intensities of the lines A, B, and α at Bosco Nero and on the Rocciamelone Mountain. In order to express the variation in the mass of air (ϵ) traversed, calculations have been made of the values at the different altitudes of $P \sec \zeta$, where P is the atmospheric pressure, and ζ is the sun's zenith distance. The following is a comparison of the values of ϵ and the mean intensities of the lines at the two stations. The scale of intensity is such that the C line = 10, and the line at 651·55 is unity.

Place of observation.	Altitude.	ϵ.	Intensities of the lines A.	B.	a.
Bosco Nero ...	1623 metres ...	1046·2 ...	50	28	3·2
Rocciamelone ...	3538 ,, ...	846·2 ...	40	20	2·2

A comprehensive bibliography of the subject accompanies the paper.

SIMILARITY OF THE ORBITS OF CERTAIN ASTEROIDS.—In the *Publications of the Astronomical Society of the Pacific*, No. 15, 1891, Prof. Daniel Kirkwood gives a list of twenty-four asteroids arranged in ten groups, according to the similarity of their orbits. The following are the groups:—

I.	84 Clio. 115 Thyra. 249 Ilse.	VI.	3 Juno. 97 Clotho.
II.	19 Fortuna. 79 Eurynome.	VII.	203 Pompeia. 200 Dynamene.
III.	134 Sophrosyne. 193 Ambrosia.	VIII.	278 Pauline. 116 Sirona. 1 Ceres.
IV.	37 Fides. 66 Maia.	IX.	245 Vera. 86 Semele. 106 Dione.
V.	218 Bianca. 204 Callisto. 246 Asporina.	X.	121 Hermione. 87 Sylvia.

Jupiter is held responsible for the perturbations necessary for the development of these groups of asteroid orbits from the primitive solar nebula.

ASTRONOMICAL AND PHYSICAL SOCIETY OF TORONTO.—The first number of the Transactions of this Society (1890-91), with which is also included the first Annual Report, has recently been issued. It contains abstracts of several interesting papers read at the meetings, among which is one on the disappearance of Saturn's rings, by Dr. Morrison, two by Mr. Shearman on coronal photography, and two by Mr. A. F. Miller on the spectroscope. A drawing of a sun-spot observed on November 30, and a hydrogen prominence measured on August 3, forms the frontispiece of the number.

A NEW ASTEROID (311).—On June 11 M. Charlois discovered the 311th asteroid. Its magnitude was 13.

THE ROYAL SOCIETY CONVERSAZIONE.

THE Ladies' *Soirée* of the Royal Society was held on the 17th instant, and was very numerously attended. The following were among the chief objects exhibited:—

Finger-prints as a means of identification, exhibited by Mr. Francis Galton, F.R.S. (1) Specimens showing the nature and character of the patterns that are formed by the papillary ridges on the bulbs of the fingers, as well as on the rest of the inner surfaces of the hands and feet. (2) Evidence of the persistence of the patterns in their essential details, however minute, from infancy to age. (3) Method of indexing a collection of finger-prints so that a determination may be quickly arrived at, whether the duplicate of a given specimen is contained in it or not. (4) Process of making finger-prints, exhibited in operation.

Registration of colours in numbers, and apparatus to show the greater sensitiveness of the eye to different colours, exhibited by Captain Abney, C.B., F.R.S., and General Festing, F.R.S. The registration consists in referring any mixed colour to a single wave-length, and a percentage of white light. With the apparatus to show the greater sensitiveness to the eye of different colours, a comparison is made by placing two colours side by side, which are at ordinary intensity of equal luminosity, and by then diminishing the intensity of each equally.

An optical illusion, exhibited by Prof. Silvanus P. Thompson, F.R.S. On two rotating disks, A and B, are spiral patterns in black and white, which seem to move radially inwards and outwards respectively. Let the observer gaze fixedly for about one minute at the centre of A, and then suddenly transfer his gaze to any object—say the face of a friend—he will see that object apparently enlarging from the middle outwards. After similarly gazing for a minute at B, and then looking at any object, he will see it apparently diminishing.

Discharge without electrodes through gases, exhibited by Prof. J. J. Thomson, F.R.S. The discharge tube in these experiments is made to form the secondary of what is essentially an induction coil, and the discharge passes round a closed current in the gas. Experiments *a*, *b*, *c*, *d* show various forms of the discharge in tubes and bulbs. *e* shows the residual glow produced when the discharge passes through oxygen. *f* shows the action of a magnetic field on the discharge; along the lines of force the discharge is facilitated, while at right angles to them it is retarded. When the magnetic field is "off," the discharge takes place in the bulb, and not in the tube; when the field is "on," in the tube, and not in the bulb. *g* illustrates the stoppage of the discharge when a gas electrically weaker than that in the discharge tube is placed in the neighbourhood of the latter.

A nickel pendulum, illustrating the effect of heat upon the magnetic susceptibility of nickel, exhibited by Mr. Shelford Bidwell, F.R.S. Nickel, which at ordinary temperatures is a magnetic metal, becomes non-magnetizable at about 300° C. A copper disk, to which a projecting tongue of nickel is attached, hangs like the bob of a pendulum from a double thread, and is deflected to one side by a magnet which attracts the nickel tongue. The heat of a spirit-lamp placed beneath the tongue quickly destroys the magnetic quality of the nickel, so that the magnet can no longer hold it; the bob accordingly falls back and performs an oscillation. On its return to the neighbourhood of the magnet, however, the tongue has cooled sufficiently to be once more attracted, but after a momentary contact it is again released, and the process is repeated. Thus the bob can be kept swinging like the pendulum of a clock.

The meldometer, exhibited by Mr. J. Joly. This instrument is for determining the melting-points of minute quantities of substances, by comparison with bodies of known melting-point. The method consists in measuring the thermal expansion of a ribbon of pure platinum when a minute quantity of a substance, dusted on its surface (and observed through a microscope), is melting. The platinum is heated by a current, and the thermal value in degrees Centigrade of its expansion found by preliminary observations, using bodies of known melting-point. The expansion of the ribbon is read by an electric-contact method. The instrument shown reads a change of 2° C. Range up to 1600° C. about. Quartz may be melted on the meldometer, and most or all of the silicated minerals.

Facsimile drawings of paintings from tombs at Beni Hasan, Upper Egypt, exhibited by Mr. Percy E. Newberry (of the Egypt Exploration Fund). A series of facsimile drawings in colour, executed by Mr. M. W. Blackden, of some of the most interesting paintings on the walls of the tombs of Ameni and Khnumhotep (XII. Dynasty, *circa* 2500 B.C.), at Beni Hasan, in Upper Egypt. These drawings are the property of the Egypt Exploration Fund.

Instrument for examining the strains in bent glass beams, exhibited by Prof. C. A. Carus-Wilson. There is a steel straining frame in which the beam to be examined is placed; this frame can be moved in any direction in its own plane between two Nicol prisms. The Nicol prisms can be rotated through any required angle. When the beam has been supported in any given manner, load is applied by a screw, and the action of the strained glass on the polarized light enables the precise state of strain all over the beam to be ascertained. The instrument has been used to determine the action of "surface loading," and to show to what extent this action affects the state of strain in beams supposed to obey the Bernoulli-Eulerian theory of flexure.

Cup-micrometer, an instrument for measuring the rate of growth of a plant, exhibited by Mr. Francis Darwin, F.R.S. A thread is attached to the upper end of the plant, passes over a pulley, and is fastened to a weight. The descent of the weight (which is a measure of the growth of the plant) is estimated by adjusting a micrometer screw carrying a small cup of oil, until a needle point on the weight touches the surface of the fluid. The method, a modification of that used by physicists to measure the rise or fall of a fluid surface, was designed by Mr. H. Darwin, of the Cambridge Scientific Instrument Company.

Electrical volatilization of metals, exhibited by Mr. W. Crookes, F.R.S.

Living animals from the aquarium of the Marine Biological Association at Plymouth, exhibited by the Marine Biological Association.

Art metal work, from the factories of Messrs. Tiffany and Co., in New York, exhibited by Messrs. Tiffany and Co. Representative articles in wrought metals; amalgamation of metals; enamelling on silver and gold.

Photographs of living corals taken in Torres Straits, exhibited by Mr. W. Savile Kent.

Prof. J. Norman Lockyer, F.R.S., exhibited:—(1) Photographs of a group of sun-spots. A series of enlargements of a group of sun-spots shown on the 12-inch sun-pictures taken under the direction of Lieut-Colonel Strahan, at Dehra Dun, India, on December 16, 18, 19, 20, 21, 22, 23, 1887. The spots have been enlarged three times, and it will be seen that great changes took place during the period of visibility.—(2) Photographs of the temples at Karnak and Edfou. These are enlargements from photographs taken in January 1891, with reference to the orientation of the temples. The photographs show that, notwithstanding the elaborate details of the architecture, the principal axes of the temples were kept perfectly clear from one end to the other.

Prof. W. Roberts-Austen, C.B., F.R.S., exhibited a new, brilliantly coloured alloy of gold and aluminium, and facsimiles of medals asserted to be of gold and of silver, transmuted from base metal by the aid of alchemy. One of the medals bears on its reverse the statement that it was struck in 1675, by J. J. Becher, in silver transmuted from lead.

Mr. Ludwig Mond, F.R.S., exhibited:—(1) Nickel-carbon-oxide. (2) Pure nickel extracted from nickel ores by means of carbonic oxide. (3) Articles of pure nickel deposited from nickel-carbon-oxide, and goods plated with nickel by exposure to nickel-carbon-oxide [$Ni(CO)_4$]. This unique chemical compound was obtained in 1890 by Mond, Langer, and Quincke, by passing a current of carbonic oxide over finely-divided metallic nickel at the ordinary temperature, and refrigerating the resulting gas. It is a colourless liquid, of high refractory power, boiling at 43° C., and solidifying at 25° C., and is split up again into nickel and carbonic oxide on heating its vapour to 180° C. It is highly poisonous; while according to Prof. McKendrick's researches it has, when injected subcutaneously in very small doses, a remarkable power of reducing the temperature of animals. The properties of this substance make it possible to volatilize nickel at a low temperature, and to extract it industrially in a perfectly pure state from all other substances with which it is found. Articles of pure nickel, and goods plated with pure nickel, are produced by exposing heated moulds or goods to nickel-carbon-oxide vapour, or to a solution of this compound in suitable solvents.

Specimens of Japanese metal work, including *Ojimé*, or sliders, *Yanoné*, or arrowheads, and *Tsuba*, or sword-guards, exhibited by Prof. A. H. Church, F.R.S.

Prof. A. Newton, F.R.S., exhibited a drawing, the first received in Europe, of *Notoryctes typhlops*, a new form of Marsupial of mole-like habit, and structure accordingly, sent by Prof. E. C. Stirling, of the University of Adelaide, South Australia. The first specimen of this remarkable mammal, one of the most unexpected discoveries for many years, was sent from the interior of South Australia by Mr. A. Molineux to Prof. Stirling, of Adelaide, who contributed to NATURE (vol. xxxviii. pp. 588, 589) such a notice of it as its imperfect condition admitted. He afterwards obtained other examples, which are fully described in a memoir communicated to the Royal Society of Adelaide. "Four or five of the cervical vertebræ are fused, and there is a keeled sternum. An enormously thick and short first rib, which serves the purpose of buttressing the sternum in lieu of coracoids. Eyes mere pigment spots, underneath the skin and temporalis muscle. It has a remarkable habit of burrowing for long distances in the sand with great rapidity." These specimens were obtained about 1500 miles north of Adelaide, but a telegram from Prof. Stirling, dated May 31, 1891, states that he has himself obtained others in the course of a journey, just completed, across the continent from Port Darwin.

Mr. Walter Gardiner, F.R.S., gave demonstrations of certain important phenomena associated with the absorption and the flow of the water taken up by plants:—(1) Root pressure. Water present in the soil, and containing minute traces of nutritive salts, is absorbed by the root-hairs so powerfully and in such quantities as to set up a considerable pressure in the interior of the plant. This "root pressure" may be demonstrated by attaching to the cut end of a stem a manometer containing mercury, or some coloured fluid. Here a solution of nigrocine in water is employed. (2) The transpiration current. Among the more important factors which determine the flow and ascent of water from the root, upwards, is the sucking force induced by the modified evaporation or transpiration of water from the general free surface of the leaves. During transpiration the water escapes as vapour, and the salts are retained for food. In this experiment the existence of a "transpiration current" is shown by allowing a cut branch to suck up milk, when the movement of the fat globules registers the flow of the liquid. (3) The amount of water absorbed by the root. This may be estimated by simple measurement, employing some such form of apparatus as that exhibited.

Engravings to "Travels among the Great Andes of the Equator," exhibited by Mr. Edward Whymper. These illustrations are selections from Mr. Edward Whymper's forthcoming work upon the Great Andes of the Equator (in which he gives accounts of the first ascents of Chimborazo, Cayambe, Antisanal, &c., &c.), and includes views on and about the equator at great elevations; incidents of travel; numerous examples of the new genera and species obtained on the journey; a facsimile reproduction of the map of Don Pedro Maldonado (upon which existing maps of Ecuador are based), and the original route survey, and map of Chimborazo, made by the author. The work, with 200 illustrations and four maps, will be published in the present year by Mr. John Murray.

Mr. W. Bateson exhibited (1) models of double supernumerary legs and antennæ in beetles; (2) mechanical model showing the usual symmetry of double supernumerary appendages in beetles. Supernumerary appendages in beetles nearly always spring as branches from a normal appendage, and are generally double, being made up of two limbs more or less compounded together. The two extra limbs are always *a complementary pair*, one being structurally a right limb, while the other is left. Commonly the symmetry of the parts is arranged as follows:—(*a*) The two extra limbs and the normal one stand in one plane, one of the extra limbs being nearer to the normal limb and one remoter from it. (*b*) The nearer is in structure and position an image of the normal limb in a mirror at right angles to the plane in which the three limbs stand; and the remoter is an image of the nearer in another mirror beyond and parallel to the first. Thus the relations of the parts in their several positions may be represented by the mechanical model exhibited, in which the extra legs, revolving round the normal leg, take attitudes proper to the positions which they occupy relatively to the normal leg.

Prof. A. C. Haddon exhibited the geographical distribution, and the progressive and retrogressive evolution, of art and ornament in British New Guinea. The exhibit is designed to show that savage art can be studied as a branch of biology, and that it is only when so treated that it yields its most valuable results. Most savage and barbaric designs have only a very limited geographical range, and those which have a wide distribution can, in the majority of cases, be proved to be homoplastic and not homogenetic. The evolution of a particular pattern must be sought in the district in which it occurs, and its developmental history can only be safely attempted when a comparison is made of numerous objects from the same locality. The foregoing propositions are illustrated by means of specimens, rubbings, photographs, and sketches of decorated objects from British New Guinea.

At intervals during the evening, the Edison loud-speaking telephone and Bell's receivers were connected with the performance of "The Gondoliers," at the Savoy Theatre, London; the Prince's Theatre, Birmingham; and with vocal and instrumental concert rooms at Liverpool and Birmingham.

Photographs of volcanic phenomena were exhibited by Dr. Tempest Anderson during the evening. These photographs of volcanic phenomena were taken last year during a visit to the Skaptâ Jokul, and other volcanic districts in Iceland. The eruption of the Skaptâ Jokul, in 1783, was one of the largest on record. A mass of lava, estimated to be equal in bulk to Mont Blanc, flowed out in two streams, each forty to fifty miles long. The actual craters situated in the desert interior of the island appear not to have been previously visited.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The following are the speeches delivered by the Public Orator (Dr. Sandys, Fellow and Tutor of St. John's

College) on June 16, in presenting for the honorary degree of Doctor in Science Sir Archibald Geikie, F.R.S., Director-General of the Geological Survey of Great Britain and Ireland; Mr. W. H. Flower, C.B., F.R.S., Director of the Natural History Museum; and Dr. Elias Metschnikoff, *Chef de Service* of the Institut Pasteur, Paris.

Salutamus deinceps virum et scientiarum et litterarum laude illustrem, in Academia Edinensi quondam Geologiae Professorem, Britanniae et Hiberniae explorationi geologicae praepositum, societatis Regiae socium, societatis geologicae praesidem, societatis denique Britannicae scientiarum terminis prorogandis praesidem designatum. Geologiae et geographiae studiosorum in manibus sunt scripta eius plurima, scientiis illis aut docendis aut illustrandis destinata. Etiam aliis loquuntur libri eius elegantissime conscripti, quorum in uno Caledoniae montes vallesque per immensam saeculorum seriem causis cotidianis minutatim exsculptas fuisse demonstrat; in altero vitam et res gestas geologi magni, quem Siluriae regem nominaverim, ea quae par est dignitate describit. Viri talis laboribus non modo geologiae fines latius indies propagantur, sed etiam populo universo studia illa praeclara commendantur.

Duco ad vos geologum illustrem, ab ipsa Regina nuper novo honore ornatum, ARCHIBALDUM GEIKIE.

Quod e sapientibus septem unus dixisse fertur, *ἀρχὴ ἄνδρα δείξει*, de hoc certe viro, per honorum cursum satis longum probato, verum esse constat. Regio Chirurgorum in Collegio, primum Museo conservando praepositus, deinde physiologiam et comparativam quae dicitur anatomiam professus, deinceps Musei Britannici aedificio novo rerum naturae studiis dedicato praefectus est. Idem societati et zoologicae, et anthropologicae, et Britannicae, maxima cum laude praefuit. In Museis autem ordinandis quam perspicax; in scientiarum studiis populo toti commendandis quam disertus; hominum in diversis generibus capitis mensura inter sese distinguendis quam subtilis; maris denique in monstris immensis describendis quam minutus. Ergo, velut alter Neptunus, intra regni sui fines etiam "immania cete" suo sibi iure vindicat: idem, anthropologiae quoque in studiis versatus, ne barbaras quidem gentes contempsit, sed, velut alter Chremes, homo est; humani nil a se alienum putat.

Duco ad vos Regiae societatis socium, virum honoribus plurimis merito cumulatum, WILELMUM HENRICUM FLOWER.

Sequitur deinceps vir, qui scientiarum in provinciis duabus, et in zoologia et in bacteriologia quae dicitur, famam insignem est adeptus. Primum Ponti Euxini in litore septentrionali zoologiam professus, multa de morphologia animalium, quae invertebrata nominantur, accuratissime disseruit. Deinde Parisiis rerum naturae investigatori celeberrimo adiutor datus, eis potissimum causis perscrutandis operam dedit, per quas genere ab humano morborum impetus hostiles possent propulsari. Nam, velut hominum in mentibus virtutes et vitia inter sese confligunt, non aliter animantium in corporibus contra pestium exercitus copiae quaedam sanitatis et salutis ministrae concertare perhibentur. Mentis quidem certamen olim in carmine heroico, Psychomachia nominato, Prudentius narravit. Inter eos autem qui corporis certamen experimentis exquisitis nuper explicaverunt, locum insignem sibi vindicat vir quidam summa morum modestia praeditus, qui, velut vates sacer, proelium illud sibi sumpsit celebrandum, in quo tot cellulae vagantes, quasi milites procursantes, morborum semina maligna corripiunt, correpta comprimunt, compressa extinguunt. Talium virorum auxilio febrium cohortes paulatim profligantur, et generis humani saluti novum indies affertur incrementum.

Merito igitur titulo nostro hodie coronatur e salutis humanae ministris unus, ELIAS METSCHNIKOFF.

AT the annual election at St. John's College on June 22 the following awards in Natural Science were made:—Foundation Scholarships, continued or increased: P. Horton-Smith, Hewitt, Blackman, Woods, MacBride, Whipple. Foundation Scholarship awarded: Villy. Exhibitions: Purvis, Trotman. Hughes Prize: MacBride. Wright's Prize: Villy. In the Natural Sciences Tripos, Part II., Capstick, of Trinity, has been awarded "special distinction" in two subjects, Chemistry and Physics. It is many years since this last occurred. MacBride, of St. John's (Zoology, Botany), and Krishnan, of Christ's (Chemistry, Botany), have gained first classes in two subjects. Of the women candidates, Miss Elliot, of Newnham (Zoology), and Miss Tebb, of Girton (Physiology), have gained first class honours.

SCIENTIFIC SERIALS.

American Journal of Science, June.—The study of the earth's figure by means of the pendulum, by E. D. Preston. The author first deals with the history of the subject, then states the quantities involved, and supports the method of study in which the figure of the earth is considered separately from its size as determined by measurement of arcs of meridian. The general results of pendulum work are discussed, and the effect of continental attraction and variations in latitude referred to. The best methods of determining the duration of a pendulum oscillation at a given temperature and pressure are also considered.—On the post-glacial history of the Hudson River valley, by Frederick J. H. Merrill. The result of the action of waves upon a shore depends upon the state of rest or movement of the shore. If the land is subject to alternate periods of rest and elevation, a series of terraces will be formed; if the land is slowly rising or subsiding with respect to sea-level, an inclined plane of erosion may be produced. Arguing from this and other facts, the author states provisionally that, after the retreat of the continental glacier from the Hudson River valley, the land stood for a long time at a lower level than at present. A gradual elevation and extensive erosion of the Champlain estuary deposits in the river valley then occurred, and was followed by a depression amounting to about 100 feet at New York, and which is apparently continuing at the present day.—On alunite and diaspore from the Rosita Hills, Colorado, by Whitman Cross.—Diaspore crystals, by W. H. Melville.—Combustion of gas jets under pressure, by R. W. Wood. Anyone who has watched a burning jet of ether vapour will have noticed that, as the pressure increases, the flame gradually retreats from the orifice and eventually goes out if the pressure is carried beyond a certain point. The author has investigated these phenomena, using various gases. A burning jet of coal gas was extinguished when the pressure was equal to 23 centimetres of mercury—that is, when the velocity of the issuing gas exceeded the speed of combustion for the mixture of gas and air.—Allotropic silver: Part iii., blue silver, soluble and insoluble forms, by M. Carey Lea. From the results given in this and preceding papers, the author is led to believe that allotropic and even soluble silver may be formed in numerous ways. The reducing agents may be either a ferrous or a stannous salt, or any one of a variety of organic substances of very different constitutions. From the solubility and activity of this substance, and the parallelism which many of its reactions show to those of silver in combination, it appears probable that silver in solution, like silver in combination, exists in the atomic form.—Note on the submarine channel of the Hudson River, and other evidences of post-glacial subsidence of the middle Atlantic coast region, by A. Lindenkohl.—Are there glacial records in the Newark system?, by Israel C. Russell. Facts are adduced in support of the negative view.—A reply to Prof. Nipher on the theory of the solar corona, by F. H. Bigelow.—On the recent eruption of Kilauea, by W. T. Brigham. This is a report of the changes that took place in the crater of Kilauea during March of this year.—Turquoise in south-western New Mexico, by Charles H. Snow.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 18.—"Results of Hemisection of the Spinal Cord in Monkeys." By Frederick W. Mott, M.D., B.S., M.R.C.P. Communicated by Prof. Schäfer, F.R.S.

While engaged in studying experimentally the connections of the cells of Clarke's column with the ascending tracts of the spinal cord in the monkey, I was surprised to find that after hemisection in the lower dorsal region the sensory disturbances produced in no way corresponded with those already obtained by eminent observers.

I was therefore led to continue my experiments, and, by the kind permission of Prof. Schäfer, I carried them out in the Physiological Laboratory of University College. My thanks are also due to him for much valuable advice and assistance.

The subject is one of great importance from a scientific, as well as from a clinical, point of view. Some years ago, a case occurred in my practice which tended to shake my faith in the absolute truth of the doctrine of complete and immediate decussation of sensory impulses in the spinal cord, as taught by Brown-Séquard.

The experiments which I have performed exhibit the following principal points of interest :—

(1) Return of associated movements after complete destruction of the crossed pyramidal tract below the lesion.

(2) That all sensory impulses do not decussate in the cord—in fact, they appear to show that certain sensory impulses, *e.g.* touch, the muscular sense, and localization in space, pass chiefly up the same side, painful impressions up both sides. A peculiar condition known as "allochiria" occurs after hemisection.

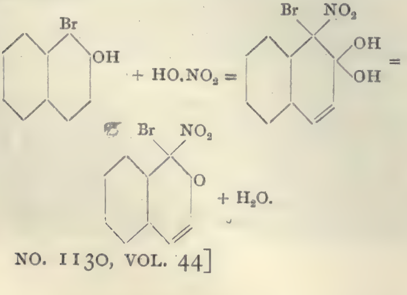
(3) The vaso-motor disturbances are *on the same side as the lesion*, and consist of vaso-dilation, swelling of the foot, and redness with rise of temperature of the skin of the foot (as compared with the opposite side), and fall of temperature in the popliteal space on the side of the lesion, due, no doubt, to paralysis of the muscles.

(4) The degenerations above and below the lesion are limited to the same side when the injury is perfectly unilateral. There are certain facts connected with the degenerations which serve to show the origin and course of certain long and short tract fibres.

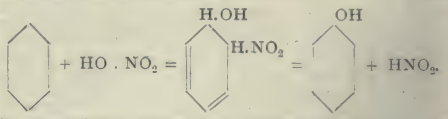
(5) Stimulation of the cortex cerebri on both sides some weeks or months after the hemisection had been performed gave, as a rule, *results* which showed that the block in the spinal cord produced by the hemisection still existed, although there had been a very complete return of associated movements.

(6) In one case ablation of the leg area on the same side as the lesion in the spinal cord was performed many months afterwards.

Chemical Society, May 21.—Prof. A. Crum Brown, F.R.S., President, in the chair.—The following papers were read :—Bromo-derivatives of betanaphthol, by H. E. Armstrong and E. C. Rossiter. The authors have completed the study of the compounds formed on brominating betanaphthol, to which they have referred in two previous notices (Chem. Soc. Proceedings, 1889, p. 71 ; 1890, p. 32). In the present paper they give directions for preparing tri- and tetra-bromobetanaphthol, and summarize the properties of the bromobetanapthols. The entire product of the action of bromine in excess on betanaphthol, has been carefully examined without any substance having been discovered which affords 1 : 2 : 3-bromophthalic acid on oxidation ; the discrepancy between the authors' observations and the earlier experiments of Smith and Meldola, therefore, yet remains to be discovered.—The action of nitric acid on naphthol derivatives as indicative of the manner in which nitration is effected in the case of benzenoid compounds generally : the formation of nitro-keto-compounds, by H. E. Armstrong and E. C. Rossiter. The chloro- and bromo-derivatives of betanaphthol when warmed with nitric acid are converted into derivatives of betanaphthoquinone ; but the formation of these compounds is preceded by that of an unstable intermediate compound. These intermediate compounds, when carefully heated, are converted into derivatives of betanaphthaquinone. Thus, when nitric acid is added to dibromobetanaphthol, suspended in acetic acid, a clear solution is obtained which, after a short time, deposits a crystalline substance ; if quickly evaporated by filtration, this product is almost colourless, but it decomposes when kept, becoming yellow. This compound, when treated with alkali, yields bromonitronaphthol. Bromobetanaphthol, in like manner, yields α_1-nitrobetanaphthol, and the tri- and tetra-bromo-derivatives yield di- and tri-bromonitrobetanaphthol. The authors are of opinion that the intermediate compounds in question are nitro-bromo-keto-derivatives, and that their formation affords evidence that the elements of nitric acid first become added to the bromonaphthol, thus :—



The theory that the formation of such addition-compounds precedes that of nitro-compounds generally, appears to afford a satisfactory explanation of a number of well-known facts which hitherto have remained unexplained. The non-production of nitro-compounds from paraffins and their derivatives appears as the natural consequence of the inability of paraffins to form addition-compounds. The theory affords a simple explanation of the formation of nitro-derivatives of *phenols* on nitrating hydrocarbons, for if the addition-compound lose $H.NO_2$ instead of $H.OH$ a phenol would result, thus—



An agent which would tend to withdraw water from the addition-compound would increase the production of nitro-compound and diminish that of phenol ; and it is known that when a mixture of nitric and sulphuric acids is used, there is less of the phenol derivative produced than when nitric acid alone is employed. A compound like the addition-compound of benzene, represented above, would obviously be unstable, and prone to undergo oxidation ; hence the explanation of the large amount of nitrous fume produced on nitrating benzene. The non-production of resinous matters when sulpho-acids are treated with nitric acid to form the corresponding nitro-compound by displacement of the SO_3H group by NO_2 is also elucidated by the authors' theory ; the addition-compound formed in such a case would very readily break up into sulphuric acid and the nitro-derivative.—A new method of preparing nitro-derivatives, and the use of nitrogen dioxide as a nitrating agent, by H. E. Armstrong and E. C. Rossiter. The authors find that the unstable compounds formed by the addition of the elements of nitric acid to the bromo-derivatives of betanaphthol yield nitro-derivatives of the naphthol on treatment with alkali, a bromine atom becoming displaced by NO_2. On treating the addition-compound with sulphurous acid, a practically theoretical yield of the nitronaphthol is obtained ; this method appears to be of general application. The authors have been naturally led to study the action of nitrogen-dioxide, NO_2, on unsaturated compounds of various kinds, in the hope of obtaining addition-compounds which by loss of HNO_2 would pass over into nitro-derivatives of the substances treated. They find that such addition-compounds are obtained, and on treatment with alkali and reducing-agents yield nitro-compounds. Thus betanaphthol yields 75 per cent. of its weight of nitro-betanaphthol ; alphanaphthol behaves similarly. Phenol yields ortho- and para-nitrophenol. The authors propose to study the action of nitric acid and nitrogen dioxide on unsaturated compounds generally from the point of view indicated in this and the previous note.—Nitrification, by R. Warington. The first section of the paper describes early experiments, showing the existence of an agent producing only nitrites, and the means of separating it from soil. Successive cultivation in ammoniacal solutions made permanently alkaline with disodium carbonate was found to be a certain method of obtaining a purely nitrous agent. Pasture soil yielded the nitrous agent more readily than arable soil. The nitrous organism was isolated by the dilution method. Cultivations were made in an ammonium chloride solution with calcium carbonate. The nitrous organism oxidizes ammonia to nitrous acid, and has no effect on nitrites. It produces nitrous acid in solutions of asparagine, milk, urine, and urea. Grown in broth containing calcium nitrate, it does not reduce the nitrate to nitrite. It requires no organic matter for its nutrition, and is apparently capable of assimilating carbon from acid carbonates. The presence of either calcium or sodium acid carbonate distinctly favours nitrification ; neutral sodium carbonate greatly hinders nitrification. The nitrous organism occurs as nearly circular corpuscles, which stain deeply. It also occurs as oval cocci, the ends occasionally more or less truncated. The remainder of the paper deals with the nitric organism. The results show that the nitric organism develops freely in inorganic solutions containing potassium nitrite, phosphates, &c., especially if supercarbonates are present. Monosodium carbonate, 1–4 grams per litre, exerted a very favourable influence ; 6 grams per litre, a retarding influence. Disodium carbonate greatly hinders the action. The nitric organism produces neither nitrites nor nitrates in ammoniacal solution. In the absence of ammonia, it energetically converts nitrites into nitrates; the presence of ammonia is apparently a great hindrance to its action. An attempt to isolate the organism failed. The nitrification performed by soil thus appears to be the work of two organisms, one of which oxidizes ammonia to nitrite, while the other oxidizes nitrite to nitrate.

Geological Society, June 10.—Sir Archibald Geikie, F.R.S., President, in the chair.—Before the commencement of the general business, Prof. Blake rose on behalf of those present at the meeting to congratulate the President on the honour that it had pleased Her Majesty to confer upon him. No one who knew him could fail to appreciate how thoroughly it was deserved; and the Geological Society would doubtless feel also the honour conferred on their science in the person of their President and the head of the Geological Survey of the United Kingdom.—The following communications were read:—Note on some recent excavations in the Wellington College district, by the Rev. A. Irving.—Notes on some post-Tertiary marine deposits on the south coast of England, by Mr. Alfred Bell. Communicated by Mr. R. Etheridge, F.R.S. The author's object in this paper is to trace the successive stages in the development of the present coast of the north side of the English Channel, and to ascertain the sources of the diversified faunas. The first traces of marine action on the south coast in post-Tertiary times, are found on the foreshore in Bracklesham Bay. The author's reading of the section is somewhat different from that of the late Mr. Godwin-Austen; and he divides the marine series into (1) an estuarine clay with Mollusca common to estuarine flats; (2) a compact hard mud; and (3) a bed of fine sandy silt with many organisms. These beds indicate a change from estuarine to deep-water conditions. A full list of the Selsey fossils is given, including, amongst other animals, upwards of 200 Mollusca. Of 35 species of Mollusca not now living in Britain, the majority exist in Lusitanian, Mediterranean, or African waters; furthermore, nearly 45 per cent. of the Mollusca are common to the older Crags of the eastern counties. The author considers the fauna of the Portland Bill shell-beds to indicate the further opening of the Channel subsequent to the formation of the Severn Straits, and believes that this fauna represents the deposits wanting between the Selsey mud-deposits and the erratic blocks which, according to him, overlie the mud; these Portland shells indicate an intermediate temperature, "rather southern than northern," according to Dr. Gwyn Jeffreys. In conclusion, details concerning still newer beds are given, and lists of fossils found therein; and the author observes that there is no evidence to show when the English Channel finally opened up, beyond the suggestion of Mr. Godwin-Austen that, if the Sangatte beds and the Coombe Rock are of the same period, it must have taken place after their formation. After the reading of this paper some remarks were made by Mr. Etheridge, Mr. C. Reid, Prof. Hull, and the author.

Mathematical Society, June 11.—Prof. Greenhill, F.R.S., President, in the chair.—The following communications were made:—Systems of spherical harmonics, by E. W. Hobson.—On the motion of a liquid ellipsoid under its own attraction, by Dr. M. J. M. Hill.—On certain properties of symmetric, skew-symmetric, and orthogonal matrices, by Dr. H. Taber.—An application of the method of images to the conduction of heat, by G. H. Bryan.—A property of the circum-circle, by R. Tucker.

CAMBRIDGE.

Philosophical Society, June 1.—Prof. G. H. Darwin, President, in the chair.—The following communications were made:—On the part of the parallactic series of inequalities in the moon's motion which is a function of the ratio of the mean motions of the sun and moon, by Mr. Ernest W. Brown.—On Pascal's hexagram, by Mr. H. W. Richmond. The author applies Cremona's method of deriving the hexagram by projection of the lines on a nodal cubic surface from the node. By use of a new form of the equation to this surface the equations of the lines are obtained in a perfectly symmetrical form, and their properties thence developed.—A linkage for describing lemniscates and other inverses of conic sections, by Mr. R. S. Cole.—Some experiments on liquid electrodes in vacuum tubes, by Mr. C. Chree. This paper describes some experiments undertaken at the suggestion of Prof. J. J. Thomson on the electric discharge through vacuum tubes in which one or both of the electrodes were liquid surfaces. The liquids employed were mercury and sulphuric acid. The electrodes when solid were of platinum or aluminium. Observations were taken of the differences presented by the discharge when the substance of an electrode was altered. The experiments were mostly at low gaseous pressures, and included observations on the character of the phosphorescence then accompanying the discharge.—On gold-tin alloys, by Mr. A. P. Laurie.—Note on a problem in the linear conduction of heat, by Mr. G. H. Bryan.

EDINBURGH.

Royal Society, June 1.—Prof. Chrystal, Vice-President, in the chair.—Prof. Tait communicated a paper, by Prof. Piazzi Smyth, on two series of enlarged photographs, one in the visible, the other in the invisible, of the violet of the solar spectrum. The paper was accompanied by the photographs. The observations include part of the spectrum as previously observed by Mr. Smyth in the summer of 1884, and extend to an extreme distance in the invisible violet. The previous observations were included in sixty plates; in the present series, twelve more plates are added in the violet region, and two independent photographs of each part have been taken. The photographs agree with those of Prof. Rowland in indicating that the Fraunhofer line, "little *d*," is either entirely absent now from the solar spectrum, or has become very unimportant.—Mr. R. Kidston read a paper on the fossil plants of the Kilmarnock, Galston, and Kilwinning coal-field in Ayrshire. All the species which are described in the paper belong, with one exception, to the Lower Coal-measures.—Prof. Tait communicated the second and third parts of a paper, by Prof. C. G. Knott, on some relations between magnetism and twist in iron, nickel, and cobalt. Part II. contains a continuation of former experiments on the twists produced in the magnetic metals when they are under the combined influence of circular and longitudinal magnetizations. A rectangular rod of cobalt twists, like nickel, left-handedly, when a current is passed along it in the direction of magnetization. Iron twists right-handedly, unless strong fields are employed. There is no reversal of the twist in nickel when strong fields are used, but a maximum can be reached. The magnitude of the twist which is produced by a reversal of one force depends upon which force is reversed. In general, reversal of the longitudinal field produces the greater effect; but iron and nickel, in low fields, twist most when the current is reversed. Hysteresis is very evident in all the phenomena. Evidence is given in this part in confirmation of the truth of an expression, which was given in Part I., for the twist in terms of the elongations in a thin-walled tube of given radius. Part III. contains a discussion of the magnetic consequences of twisting a magnetized wire—more especially a circularly-magnetized wire. The peculiar manner in which the magnetic change sometimes lags behind the stress, sometimes shoots ahead of it, is fully investigated. This effect is found to depend upon the strength of the current, on the amount of the twist, and on the amount of vibration to which the wire is subjected. The longitudinal polarity which is acquired when a wire carrying a current is twisted appears to be high in comparison with the intensity induced at the circumference of the wire. This seems to indicate the existence of molecular groupings which alter their configuration when subjected to change of stress or of magnetic force. The effects which are observed when an apparently demagnetized wire is subjected to twist suggest that a magnetized wire may in certain circumstances consist of alternate layers of opposite polarities. Any stress which acts differently on these layers will produce powerful magnetic effects. From his own experiments and those of other observers, Dr. Knott concludes that the first effect of a shearing stress on the molecular groupings is not only to increase the average intensity in the direction of the magnetizing force, but also to bring into prominence a relatively high intensity in directions at right angles to it.—Dr. Buchan communicated a paper by Mr. R. T. Omond, Superintendent of the Ben Nevis Observatory, and by Mr. A. Rankin, assistant observer, on the winds of Ben Nevis. The exact determination of northerly winds is not very easy, owing to the shape of the hill. The cliff, 2000 feet in height, which forms the northern face, breaks these winds up, and makes them squally and uncertain. Some may be entered on the record as north when they should really have been entered as north-east or north-west. Southern winds are on the whole slightly more frequent than northerly winds are. At sea-level the most frequent wind is west; and south-west, west, and north-west include nearly half of the total observations—more than half if calms are excluded. These low-level winds are in exact accordance with the distribution of barometric pressure over the British Isles according to the Buys Ballot's law, which asserts that the winds blow counter-clockwise round areas of low pressure, such an area lying to the north of the British Isles. But the Ben Nevis winds do not fit in with such a distribution of pressure at all, which indicates that isobars drawn at the level of Ben Nevis (4400 feet) have directions differing entirely from the directions of sea-level isobars. In other words, the distribution of average barometric pressure which extends over the North Atlantic and North-western Europe, and dominates the surface wind over that area, does not in this country extend to a vertical height of one mile. Precautions were taken to make certain that this difference was not due to a difference between the methods of observation at Ben Nevis and at low-level stations. If a cyclonic storm of small area is lying to the north-eastward, the sea-level winds are west or north-west; but the Ben Nevis winds may be north-east, blowing straight out from the centre of the area of low pressure. In larger storms the Ben Nevis winds are practically identical with the sea-level winds, which indicates that a storm has a vertical extent proportionate in some way to the horizontal area which it covers. The outflowing wind seldom or never occurs when the centre is to the south or west, but only when it is to the north or east; and it is most strongly marked when an anticyclone lies on the other side. The outflowing current seems to carry the ascending air of the cyclone to the descending anticyclonic regions. The non-observation of the outward current when the centre of the cyclone lies on the south or west may be due to the fact that it passes at a higher level than the top of the mountain, for it then consists of air passing from hotter to colder regions, which will presumably rise to a higher level. The veering of the wind at great heights, which should occur according to the usual theory of cyclones, is very rarely observed.—Dr. Crum Brown read a paper, by Dr. A. B. Griffiths, on the blood of the Invertebrata.

PARIS.

Academy of Sciences, June 15.—M. Duchartre in the chair.—On the deformation and extinction of isolated or periodic aërial waves propagated in the interior of delivery tubes without water and of indefinite length, by M. J. Boussinesq.—On a volatile compound of iron and carbonic oxide-iron-carbonyl, and on nickel-carbonyl, by M. M. Berthelot. The author finds that iron, taken in a particular state, combines directly with carbonic oxide at ordinary temperatures (about 45° C. gives the best results) to form a very volatile compound. The required state is attained by reducing precipitated iron peroxide by hydrogen, or by decomposing ferrous oxalate by heat, and completing the reduction with hydrogen. Iron-carbonyl is analogous to nickel-carbonyl, discovered by Mond, Lang, and Quincke (Journ. Chem. Soc., vol. lvii. p. 749, 1890). M. Berthelot has investigated the stability of the latter compound and its reactions with oxygen, sulphuric acid, ammonia, and nitrogen dioxide.—*Résumé* of meteorological observations made at Ecorchebœuf, near Dieppe, from 1873 to 1882 by M. J. Reiset.—Observations of Wolf's periodic comet, made at Paris Observatory (West Tower equatorial), by M. G. Bigourdan. Two observations for position were made on June 12. It is remarked that the comet is a round nebulosity about 20′ in diameter, and having a magnitude 13·3.—Observations of the new asteroid (310) made at Paris Observatory with the East Tower equatorial, by Mdlle. D. Klumpke. An observation for position was made on June 12.—Eclipse of the sun of June 6; observations made at Lyons Observatory, by MM. Gonnessiat and Le Cadet. Measures were made of times of contact.—Observations of Wolf's periodic comet (1884, III.), made at Algiers Observatory with the Foucault telescope of 0·50 metres aperture, by MM. Rambaud and Sy. Eight observations for position were made between May 15 and June 8.—Eclipse of the sun of June 6, observed at the Observatory of the Flammarion Scientific Society at Marseilles, by M. Jacques Léotard.—On the two forms in which the co-ordinates of the surface of the fourth degree, described by the summits of cones of the second order which pass through six given points, are expressed by means of θ functions of two arguments, by M. F. Caspary.—On an electric indicator for the detection of small variations of pressure in currents of gas, by MM. G. and L. Richard.—Researches on the application of the measure of rotatory power to the determination of compounds formed by aqueous solutions of mannite, with acid molybdates of soda and ammonium, by M. D. Gernez. By measuring the proportions of salts in solution which give the maximum rotatory effect on polarized light, the author arrives at the molecular formula of the compounds formed.—On quinethyline, a homologous base of quinine, by MM. E. Grimaux and A. Arnaud.—On ureides derived from normal acids, by M. C. Matignon.—Mode of formation of methyl-campho-carbonates of methyl and ethyl, by M. J. Minguin.—On nitro-cyanacetic ethers, by M. P. Th. Muller.—Bleaching of cotton by oxygenated water, by M. Prud'homme. The addition of calcined magnesia to oxygenated water improves the bleaching properties of the latter. According to the author, the superiority of the results obtained is due to the formation of a peroxide of magnesium.—*Rôle* of the nucleus in the formation of the fundamental muscular reticulum of the larva of Phrygane, by M. CRYSTALLOGRAPHY.

Elements of Crystallography for Students of Chemistry, Physics, and Mineralogy. By George Huntingdon Williams, Ph.D., Associate Professor in the Johns Hopkins University. Second Edition, Revised, pp. 246, with 383 Woodcuts and 2 Plates. (London: Macmillan and Co., 1890.)

THE position which crystallography ought to occupy in a scheme of scientific education is far from being generally recognized. Every day the importance of this branch of science, not only to the mineralogist and geologist, but also to the physicist and chemist, is becoming more deeply felt; and yet, as a general rule, the systematic study of crystallography is left quite unprovided for in our schools and Universities.

If we take any standard treatise on physics, we shall find that the subject of the measurement and calculation of crystal forms is almost, if not entirely ignored; and though it is, of course, absolutely impossible to discuss optical and other physical phenomena without reference to the wonderfully suggestive relations which exist between the properties resulting from internal molecular structures, and the crystalline forms which are the "outward and visible sign" of such molecular structure, yet the references are usually vague and, not unfrequently, misleading. In confirmation of this statement, it may be mentioned that in a very widely-used treatise on physics—one that has passed through many editions in this and other countries—there is a hopeless confusion between the terms "hemihedrism" and "hemimorphism" in the account which is given of the remarkable phenomena of pyro-electricity.

Nor, as a rule, have chemists dealt more adequately with the subject of crystallography than their brethren the physicists. In many chemical treatises we find such terms as pyramidal, prismatic, octahedral, rhomboidal, &c., employed so loosely as not to give the student the faintest idea of the real symmetry of the forms which are referred to. This neglect of crystallography by chemists is seen to be the more serious when we remember two important circumstances—first, that crystallization is often the only means which chemists possess of isolating and readily distinguishing many bodies; and secondly, that new substances are being continually formed by the chemist, the study of some of which may throw new and important light upon crystallographic principles.

Mr. Fletcher, in a very suggestive address to the Mineralogical Society, has justly remarked:—

> "Hitherto, at least, the chemists of this country have been too content, either to leave the crystalline forms of their artificial products undetermined, or to impose the task of their determination on the already sufficiently occupied mineralogist. It seems obvious that in a satisfactory system of education every chemist should be taught how to measure and describe the crystalline characters of the products which it is his fate to call into existence. . . . A knowledge of the elements of crystallography, including the mechanics of crystal-measurement, ought to be made a *sine quâ non* for a degree in chemistry at every University."

The consequence of this neglect of crystallography by physicists and chemists has been that the teaching of crystallography has fallen almost entirely into the hands of mineralogists and geologists. But there is no more reason why every book on mineralogy should commence with a crystallographic treatise, than that it should include dissertations on refraction or articles on chemical analysis. "Crystallography should be taught as a special subject," and the student who, after his training in physics and chemistry, takes up the subject of mineralogy, ought to know at least as much of the measurement and symmetry of crystal forms, as he does of the effects of various media on different kinds of radiant energy, or the reactions of the several bases and acids.

It would be easy to show that, much as mineralogists have done for the study of crystallography, the latter science would have been developed more logically, and perhaps more rapidly, if the illustrations of the phenomena of crystallization had not been so exclusively sought among natural products. We find not a few examples in the terminology of the science of the effects of this one-sided growth of crystallography.

Crystallography is based upon purely mathematical considerations, and the study of the principles of crystal-measurement, the discussion of crystal-symmetry, and the calculation of fundamental forms, ought clearly to be one of the first branches of applied mathematics to be taken up by the student of physics; thus the study of crystallography should certainly precede that of physical optics. If this course were followed, the student of chemistry and mineralogy would come to the teachers of those sciences with such an amount of preliminary information as would enable him to profit by their instructions.

In the work now before us, Dr. Williams fully recognizes the importance of the principles for which we have been contending, and has endeavoured to supply English-speaking students with a short and clear treatise on the principles of crystallographic science. It is certainly remarkable that the countrymen of Wollaston, Whewell, and Miller should have had to wait so long for a work of this character; though every student of the subject must gratefully remember the aid afforded by the admirable little primer prepared some years ago by Mr. Gurney, and published by the Society for Promoting Christian Knowledge.

Of Dr. Williams's qualifications for undertaking a work of this kind it is unnecessary to speak. His numerous original researches afford abundant evidence of his devotion to crystallographic study, and in the preparation of the work he has had the advice and assistance of one of the first crystallographers of the United States, Prof. S. L. Penfield, of New Haven.

In order to keep the work within the smallest possible limits, it has been restricted to geometrical crystallography, but otherwise the work has been modelled upon the same lines as Groth's standard work, "Physikalische Krystallographie." The plates and very numerous woodcuts afford the greatest possible aid to the reader, and the typography leaves nothing to be desired. In looking through this revised edition, we are struck with the almost entire absence of those typographical errors that so easily creep into a work of this kind, and which, though so obvious to an expert, often prove to be a source of infinite trouble to the beginner.

In dealing with the vexed question of crystallographic notation, we think Dr. Williams has exercised a very wise discretion. The simple and easily understood symbols of Naumann have been employed in the first instance, but in almost every case the corresponding symbol of Miller's system has been added in brackets. While all students of physics, chemistry, mineralogy, and geology ought to equip themselves with such an amount of crystallographic knowledge as may be derived from the study of this book, only a very small proportion of them are likely to be called upon to deal with the higher and more complicated problems of the science. The small minority of students who devote themselves to purely crystallographic researches may be fairly recommended to employ from the first the beautiful method of notation devised by Whewell and perfected by Miller; but it is more than doubtful if the student with a smaller amount of mathematical training would gain any real benefit from such a course. In an appendix, "on zones, projection, and the construction of crystal figures," the author of this work has indicated to such a beginner the nature of some of the methods of investigation which are pursued by more advanced students.

In any future edition of the work—and such, we feel sure, will certainly be called for—we think that the author would do wisely to add a table showing the symbols of the chief forms according to all the different systems of notation commonly employed. The student who turns to the classical memoirs of Des Cloizeaux, Mallard, Bertrand, and others of the French school of crystallography, would thus be enabled to avail himself of much valuable literature, which, owing to the employment of an unfamiliar notation, must otherwise remain a sealed book to him.

We have spoken regretfully at the outset of this notice of the general neglect of crystallographical studies; but we are compelled to admit that, for this neglect, crystallographers themselves are largely to blame. The confusion produced by numerous rival systems of notation is answerable for much of that feeling of despair among those who attempt to make themselves acquainted with the subject. If the time has not yet arrived when a uniform crystallographic language can be agreed upon, much might be accomplished if the plan adopted by the author of this work of giving in every case the symbols according to *two* systems were followed. This is already done in the *Zeitschrift für Krystallographie*, the *Neues Jahrbuch für Mineralogie*, &c., the Journals of the English and French Mineralogical Societies, and several other well-known periodicals. If a conference of the leading crystallographers of Germany, France, and England could be held to decide upon the order in which the axes should be taken in writing symbols and other similar arrangements which are purely conventional and arbitrary, we might hope to see much of the confusion removed that has so long been a bar to the progress of this most fascinating and important branch of science.

We feel assured that the simultaneous publication in this country and in America of so simple and at the same time so accurate a text-book of the subject as the work we are now considering will do much towards reviving and diffusing a taste for the study of crystallography The student who masters the contents of this little book will undoubtedly have much more to learn before he is competent to deal with all the higher problems of crystallographic science; but, however far his researches may be carried in the future—and this is, perhaps, the very highest praise we can give to the book—he will certainly have little, if anything, to *un*learn.

JOHN W. JUDD.

PHOTOGRAPHY IN COLOURS.

Photographie des Couleurs par la Méthode Interférentielle de M. Lippmann. By Alphonse Berget. (Paris: Gauthier-Villars et Fils, 1891.)

THIS interesting little *brochure* contains an account of the recent achievements in colour photography which have been made so widely known to the English public through the daily papers. Coming from the pen of an "attaché au Laboratoire des Recherches (Physique) de la Sorbonne," we may take this contribution as an authorized exposition of M. Lippmann's work, and as such it will be found useful by physicists, chemists, and photographers, as well as by the general reader who wishes to know the real state of the case concerning this important departure in photographic methods. In a short historical introduction the author calls attention to the previous photochromatic attempts by Seebeck in 1810, by Herschel in 1841, by Edmond Becquerel in 1848, by Niepce de St. Victor in 1851 to 1866, and by Poitevin in 1865. It is stated that these and all similar attempts were based upon purely chemical methods, the investigators seeking for some sensitive compound which would give chromatic impressions corresponding to the colours impinging on the film. M. Berget adds the important remark: "*a priori*, ce problème est irréalisable."

Chapters ii. to v. are devoted to elementary optical principles. Chapter ii. deals with vibratory movements and their propagation, wave-length and period, and sonorous waves. In the third chapter the phenomenon of interference is described and explained; in the fourth chapter we have sections on the luminiferous ether, the velocity of light, the decomposition of white light by a prism, and Fresnel's theory of the spectrum colours. The subject of complex colours, as distinguished from the pure colours of the spectrum, is also dealt with in this chapter, and is of special importance in connection with the colours of natural objects, to which the author devotes a short section. It is pointed out that the principle of superposition of vibrations holds good in optics as in acoustics, and that just in the same way that the diaphragm of a phonograph can take up and faithfully transmit the extremely complex system of superimposed aërial vibrations produced by the human voice, so the ether transmits the complex superimposed vibrations emanating from coloured objects. In connection with the history of the undulatory theory, the whole credit is given to Fresnel: "L'honneur de donner la première théorie rationelle de la lumière, en la considérant comme résultat d'un mouvement ondulatoire, était réservé à un savant français: Fresnel." We should like to have seen Thomas Young receive at least an honourable mention.

The subject of interference receives more detailed treatment in chapter v., the interference of direct and reflected waves, and the theory of Newton's rings, being specially dealt with. It is not till we come to the sixth chapter that we are introduced to the main subject of the *brochure*. The principle which guided M. Lippmann in his experiments is well and tersely given. Imagine a plane metallic mirror with its reflecting surface coated with a transparent, homogeneous film of a silver haloid in albumin or collodion. Supposing a coloured ray of definite wave-length to fall on such a film, the undulations would traverse the transparent sensitive film, and being reflected from the polished surface of the mirror, and meeting the incident waves, would produce interference. The space in front of the mirror would thus be occupied by parallel planes alternately light and dark, and separated by half wave-lengths, *i.e.* by spaces of 1/4,000,000 of a millimetre. There is therefore ample space, even within the thickness of the film, for several of these planes of interference. On development, the planes corresponding to the light intervals would alone give films of metallic silver, while the dark intervals would remain unaffected. On fixing, there would thus be left in the film a series of parallel films of metallic silver separated by half wave-lengths. Any pair of such films constitute a thin plate in the Newtonian sense, and will give by interference a colour corresponding to that which produced the original deposition of the films when viewed by reflected light.

To realize the foregoing principle experimentally, M. Lippmann has found it necessary to use dry films of collodion, or albumin, or gelatine sensitized by immersion, as in the old wet collodion process: emulsions are granular and opaque, and contain particles which are gross in comparison with the half wave-length of a spectrum colour, and cannot be used. Moreover, it has not been found practicable to coat the reflecting surface of the mirror directly with the sensitive film, because the free iodine tarnishes the silver and destroys its reflecting power. This difficulty has been surmounted by making the coated glass plate one side of a shallow trough with parallel sides filled with mercury, the coated side being inwards, and in close contact with the mercury. The conditions for reflection and interference are thus fulfilled. The image of the spectrum is focussed on a glass plate with a ground surface, which is temporarily fixed to the side of the cell or trough in the same position as that occupied by the sensitive plate, *i.e.* with the ground surface inwards. After focussing, the ground glass is removed, and the sensitive plate substituted for it in the position described.

The spectrum was produced by an electric arc light of 800 candle-power, and the time of exposure for the different parts of the spectrum was regulated by interposing cells with coloured solutions, beginning with a solution of helianthin which transmits only the red and yellow, then replacing this by a cell of potassium dichromate which transmits the red, yellow, and green, and then finally exposing for a few seconds without any screen, so as to impress the blue and violet. The whole time of exposure varies, according to the sensitiveness of the film, from half an hour to two hours. The details of development and fixing are given by M. Berget, and do not differ fundamentally from the ordinary methods. The finished image, *when dry*, shows the spectrum colours by reflected light with metallic brilliancy, and as the colours are purely optical, depending only on reflection and interference, they are permanent. As the author points out, it is certainly a marvellous tribute to the fidelity of the photographic method that a series of laminæ of metallic silver separated by intervals of only about 1/4,000,000 of a millimetre should retain their positions with optical accuracy during the processes of fixing and development.

There can be no doubt—as will be admitted by all who have seen the results—that M. Lippmann is to be congratulated on having made a most important advance in the methods of photochromy. How far his experiments go towards the realization of the great problem of photographing objects in their natural colours is a question quite distinct from his present achievement. M. Berget tells us that satisfactory reproductions of coloured glasses illuminated from behind by the electric light have been obtained, but this is only a very little step in the desired direction.

"Que reste-t-il à faire pour rendre *absolument usuel* le procédé photochromique de M. Lippmann?" There remains a great deal! Not the least of the requirements is a transparent sensitive film equally sensitive to every colour of the spectrum, and sufficiently sensitive as a whole to enable the impression to be secured with a moderate exposure, instead of 30 to 120 minutes. Till this is accomplished we are not much nearer the solution of the problem of photography in natural colours than we were before. M. Berget speaks hopefully of the prospects in this direction, and we wish every success to his anticipations. But it is no detraction from the merit of M. Lippmann's results if these have no immediate bearing on practical photographic processes. As a triumph of physical science these experiments will live.

"C'est aussi un triomphe pour la science française, car ce mode de reproduction des couleurs du spectre à l'aide des lames minces limitées par des plans d'argent constitue une matérialisation, réalisée par un savant français, de ces ondes lumineuses conçue pour le première fois par le puissant génie d'un autre Français illustre: j'ai nommé Augustin Fresnel."

With this patriotic outburst M. Berget concludes his pamphlet, and the compatriots of Niepce and Daguerre may well be gratified with this latest emanation from the physical laboratory of the Sorbonne.

R. Meldola.

OUR BOOK SHELF.

Geometry of Position. By R. H. Graham, Author of "Graphic and Analytic Statics." (London and New York: Macmillan and Co., 1891.)

This work essays to fill an existing want by providing an English text-book on the important subject of geometry of position in relation to graphical statics.

The author gives an introductory chapter on anharmonic pencils and ratios, followed by an interesting chapter on projective conics, and devotes the remainder of the book to the application of graphic methods to statical problems, including, amongst others, the discussion of Maxwell's theory of reciprocal figures.

The chapter on anharmonic pencils and ratios would have been considerably improved by the introduction, at the beginning, of more definitions and explanations of the nomenclature adopted. The proofs of Desargue's theorem and its converse, given on p. 3, are unduly compressed, considering the early stage at which they are introduced; and the student's preliminary difficulties will be increased by the fact that the enunciations have been given in succession, while there is nothing to indicate which is to be treated first.

In the chapter on reciprocal figures, we would suggest that the proof given of Theorem I., Art. 50, might with advantage have been dispensed with. In Art. 52 it is erroneously assumed that OB′ is equal to force (1); this assumption mars a proof which would be otherwise good.

The work exhibits evidence of originality, and it is, perhaps, to be regretted that the proof-sheets have apparently been revised only by the author himself. Their revision by one who had no part in compiling them would probably have contributed to a better arrangement, and to the exclusion of much that is vague.

The carefully drawn diagrams of different problems contained in the book form admirable illustrations to the non-technical reader of the nature of the operations involved in the application of the graphical calculus, and of the character of the results obtained by it. They are the more welcome as such information is not readily available in English text-books, while in foreign treatises it is often developed in such minute detail as to make the foundations nearly inaccessible to the general reader.

A word of praise is due to the interesting collections of examples at the ends of the chapters, which are, it seems, mostly original, but partly drawn from sources not often laid under contribution in the ordinary text-books.

ALEX. LARMOR.

The Species of Epilobium occurring North of Mexico. By Dr. Trelease, Director of the Missouri Botanic Garden. From the Second Annual Report of the Garden, issued April 1891. 48 pages, 48 plates.

EPILOBIUM is not a very large genus, but is spread universally through the north temperate zone, both amongst the plains and mountains, and reappears in plenty in New Zealand. The species are very difficult of delimitation and definition, and great diversity of opinion has prevailed as to their number, and the validity of the characters which have been used to characterize species. It is evident, moreover, that many of them hybridize freely in nature. Passing over the earlier well-known writers, such as Pursh, Muhlenberg, Hooker, and Gray, in 1876 Barbey contributed a monograph of the Californian species to Brewer, Watson, and Gray's "Flora of California," and later published excellent figures of the new species which he there described. In 1884, Haussknecht published a monograph of the whole genus. Of the 38 species dealt with in Dr. Trelease's paper, 13 have been proposed by Haussknecht, 3 by Barbey, 4 by himself, and one by Parish, so that more than half the 38 have been lately described for the first time. Dr. Trelease describes fully all the species known in Temperate North America, gives an octavo plate of each of them, and a detailed account of their geographical distribution, citing the numbers of all the recent collectors. Of the 38 species only 9 extend their range beyond the American continent. The paper will be a very acceptable contribution to our knowledge of a difficult genus, and will no doubt be incorporated in the new "Flora of North America," of which the second volume is already published, and the first and third of which we anxiously wait for.

J. G. B.

A Guide Book to Books. Edited by E. B. Sargant and Bernhard Wishaw. (London: Henry Frowde, 1891.)

THERE are so many books of all kinds that ordinary readers may be excused if they are sometimes at a loss as to the works which they ought to select for study. The editors of the present volume have come to the aid of such readers, and may be congratulated on the manner in which they have accomplished a useful but most troublesome task. They make no attempt, in a philosophical sense, to classify the various subjects with which authors have dealt; they simply take these subjects one after the other, in alphabetical order, and set down what seem to them the best books relating to each. Taking into account the amount of space at their disposal, they probably could not have chosen a plan that would have been more readily intelligible. Of course opinions will differ about the value of the works included in the several lists. Everyone who consults the volume will be of opinion that the editors have omitted some things which they ought to have noted, and that they have noted some things which they ought to have omitted. But there cannot but be a general agreement that, upon the whole, the selection has been made on sound principles, and that it is likely to be of real service to very many of those who may have occasion to refer to it. A large number of eminent writers have helped the editors, not only by drawing up lists of books, but by giving them much valuable advice.

Tasmanian Official Record, 1891. By R. M. Johnston, F.L.S. By Authority. Second Year of Issue. (Tasmania: William T. Strutt, Government Printer, Hobart, 1891.)

ANYONE who may wish to obtain information about Tasmania will be hard to please if he does not find what he wants in this elaborate volume. It begins with an account of the general physical outline of the island, and then we come to Tasmanian history, and to the Tasmanian constitution and government. After a chapter on Crown lands we are invited to consider the geology and mineral products of Tasmania, its flora and vegetable products, fauna and animal products, population, vital statistics, trade and interchange, accumulation, finance, production, law, crime, and protection, and "intellectual and social provision." The work is wound up with a view of the progress of Australasia, and a summary of general statistics. In the present issue some important additions have been made to the book as originally published, and by devoting attention to classification the editor has tried to "obviate any difficulties that might arise from the necessity of bringing together in one volume such a variety of subjects."

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Albert University.

PROF. LANKESTER, in the interesting letter published in NATURE for May 28 last (p. 76), expresses his desire to have "a genuine professorial University set on foot in London, not because it is London, but because University and King's Colleges are there, and respectfully petition Her Majesty to do for them what the monarch has done in past days for other Universities."

I have not seen the petition of the Colleges. But I have before me the draft charter adopted by their Councils, which I presume is intended to give effect to the prayer of the petition. I can hardly imagine that Prof. Lankester was acquainted with its contents when he penned the sentence which I have quoted.

If the Albert University is called into existence—and it seems very probable that its charter will be granted—it will be an institution very similar to what the University of London was in the early years of its existence, when it drew its candidates only from the so-called affiliated Colleges.

The charter commences by reciting "that it is expedient there should be constituted in and for the London district (defined as 'a radius of fifteen miles from Somerset House') a University . . . commending to its students systematic courses of teaching and methods of study." But "commending" is what we all do now.

The new University is to be of the federal type. Beginning with University and King's, "other Colleges may from time to time be admitted." This was inevitable, though my pointing out the fact made my friend Prof. Lankester somewhat angry.

Any medical school may be admitted which is recognized as efficient by any qualifying body under the Medical Acts. But while Colleges will have representatives on the Council, the medical schools will only have representatives on the Faculties.

Degrees may be granted apparently in any subject the Council please, subject to a regular course of study and examination. This will apparently admit theology, which is probably a desirable thing, provided it be unsectarian.

The powers to grant degrees are rather large, and deserve careful consideration. The London radius at once, as has been the case with the existing University, goes off into Imperial infinity in the provision that anyone who has been a resident student in any University in the Empire may count his time and examinations, except that a "final portion of the period of study" and the "final examination" shall be passed in the University.

There is an unlimited power to grant *ad eundem* degrees as well as honorary degrees at the discretion of the Council. Fellows of University and King's Colleges (a purely honorary distinction in itself) are indicated as fitting recipients, and also "past students of the said Colleges," a rather large door to open if in the future a degree is to have any meaning at all.

Power is taken to examine into the efficiency of schools or any academic institutions—work already in the hands of other Universities—and apparently the London radius again becomes infinite.

Independent University lecturers may be appointed.

The Council will consist of members appointed for five years by (1) the Crown (Lord President); (2) Convocation; (3) Colleges; (4) Colleges of Physicians and Surgeons; (5) Faculties. The Faculties are to be constituted (1) of teachers in the Colleges; (2) of examiners; (3) of persons who are or have been engaged in University teaching in London. The Boards of Studies are delegations from the Faculties, as they should be. All this is much on the lines sketched out in my own letter in NATURE.

A rather remarkable feature in the scheme is the creation of a Convocation of graduates. Whatever may be the function of this body in other Universities, it is somewhat surprising to meet with its existence in what professes to be a teaching University.

The examinations are to be conducted by examiners who are members of the respective faculties associated with external examiners; the teacher-examiner seems not to be insisted upon.

These are the essential elements of the proposed constitution. If it is asked what distinctive character the Albert University will possess which will mark it off from the existing University, or from that body as it might be conceivably reconstituted, I must confess that it seems to me to lie in a very small compass. Notwithstanding the use of the ambiguous word "commending," when one would have expected "prescribing," I take it for granted that the essential feature in the whole scheme is the enforcement upon candidates for degrees of attendance upon a curriculum. But in the existing University, this is already required in the Faculty of Medicine. Prof. Huxley has further urged it in the Faculty of Science; and for my part I believe that the time has arrived when it might be demanded without difficulty. The prominence given to practical work in the science examinations has made it all but impossible for a candidate to acquit himself successfully who has not attended a competent course of instruction. To insist upon a curriculum would be now scarcely more than the practical recognition of this fact. The only real point of divergence is in the Faculty of Arts; about this I speak with some hesitation. It may be that the enforcement of a curriculum is desirable; I am not satisfied that in this faculty it is so, or at any rate absolutely essential, as I think it is in the Faculty of Science. With this exception I can see no net public gain in the new scheme to justify the creation of the cumbrous machinery of a new federal University.

Seeing that the existing University is a State institution in actual possession of the field, I think the public at large might have reasonably expected from the Senate some statesmanlike criticism, rising above the petty level of supposed self-interest in the very serious action which the Government is apparently about to take.

They content themselves, however, with a sort of half-sulky acquiescence in the scheme "so far as it proposes to confer on the petitioning Colleges the power of granting degrees in arts and science to students of the Colleges who have pursued their entire academic curriculum within the Colleges." The Senate, a little maliciously, proceeds to point out that "the petition of the Colleges lays great stress upon the paramount importance of close association of students and teacher-examiners, and of placing the power of granting degrees in the hands of those teachers who have instructed the candidates." It not unnaturally insists upon the inconsistency with this position of the proposal "to accept residence and examinations at other Universities," if only a final period of study, "which might be a short attendance at evening classes," be passed at the new University.

It also objects to the honorary and *ad eundem* degrees. But its criticism is even more destructive in regard to the Medical Schools. It is quite obvious that if the Medical Schools joined the Albert University, the teacher-examiner system would disappear, and the new and the old Universities would be simply competing agencies for doing the same kind of work in the same kind of way. The same argument applies more or less to the other faculties as soon as the number of constituent Colleges becomes numerous.

Yet so great is the magic of a phrase that the daily papers in reporting the proceedings in the Privy Council describe the scheme as that of a Teaching University. A University of the Scotch or German type may have some claim to that title; but no federal University can ever possess a valid one, for the simple reason that there will always be a morphological distinction between the Colleges which teach and the University which examines and grants degrees.

Prof. Lankester contended in his letter that the question whether University and King's Colleges should have a University Charter was a sort of private affair between them and the Government. But I do not think this view can be accepted. Whether we like degrees or whether we do not, they have a certain value in the eyes of the public. Personally, I have no objection to the multiplication of Universities, if each has a proper geographical area assigned to it. But the multiplication of Universities in the same place seems to me a great evil. It cannot be assented to without the necessity being shown to be overwhelming. And in the present case it appears to me that it cannot be so shown. If the existing University is so injurious to the best interests of the higher education that another is imperatively demanded to do the work in which it fails, then it appears to me that two obvious points present themselves:—

(1) The new University should be free from the defects that attach to the old one. Prof. Lankester speaks of the "thraldom" of "the Imperial centralizing institution"; but when the matter comes to be looked into, the new institution also proposes to be Imperial and centralizing, and will be found to exercise the same or even greater thraldom on the individual teacher.

(2) If the old University is really doing mischief, it is the paramount duty of the supreme Government, whose creature it is, to reform it. The fact that the Senate and Convocation are at loggerheads how this is to be effected is really beside the question. When public opinion demanded the reform of the older Universities, new ones were not created alongside the unreformed old ones; but a Commission with executive powers effected the changes which were necessary. And for a similar procedure there is still time at Burlington Gardens.

The Holarctic Region.

REVIEWING the recently-published "Introduction to the Study of Mammals" by Prof. Flower and Mr. Lydekker, Prof. Lankester states (*suprà*, p. 122) that "The authors of the present work mention Dr. Heilprin's opinion that the Palæarctic and Nearctic regions should be united and called the Holarctic region. But they do not adopt this opinion, nor refer to Huxley's proposal to term this same area Arctogæa," and so on. Now, in this last statement my good friend the reviewer, perhaps writing from memory, is mistaken. Had Prof. Huxley proposed to limit his "Arctogæa" to the Palæarctic and

Nearctic regions of Mr. Sclater and Mr. Wallace, I should certainly not have suggested to Prof. Heilprin a new name for that combination. Anyone looking to the passage (Proc. Zool. Soc., 1868, pp. 314, 315) in which Prof. Huxley defined his "Arctogæa"—a name to which, let me say, I have not the least objection—will see that it signifies that part of the world which is not "Notogæa," and therefore includes the Ethiopian and Indian regions of Mr. Sclater, whereas my "Holarctic" region expressly excludes them, and is therefore a very different thing from "Arctogæa" in its true sense.

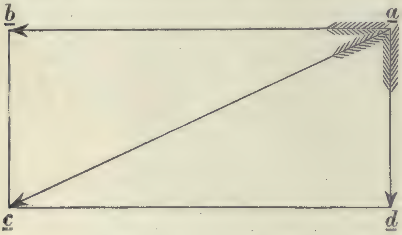
Force and Determinism.

IN your issue of March 12 (vol. xliii. p. 491), Dr. Oliver J. Lodge characterizes as "perfectly correct" the statement "that, although expenditure of energy is needed to increase the speed of matter, none is needed to alter its direction." I have looked in vain for some notice of this apparently strange doctrine in your subsequent issues, with the exception that Prof. C. Lloyd Morgan (April 16, p. 558) objects that the direction of motion cannot be changed by purely metaphysical means, or will-power. But passing over this rather important and interesting point with only the observation that Sir John Herschel thought differently—thought, in fact, that "without the power to make *some* material disposition, to originate *some* movement, or to change, at least temporarily, the amount of dynamical force appropriate to one or more material molecules, the mechanical results of human or animal volition are inconceivable" (*Fortnightly Review*, July 1, 1865, vol. i. p. 439)—I desire to call a moment's attention to the first statement alluded to.

Dr. Lodge admits that "expenditure of energy is needed to ncrease the speed of matter." But, as a matter of fact, is it not very difficult, if not indeed practically impossible, to change the direction of a moving body without affecting its speed? "A force at right angles to motion does no work," says Dr. Lodge. Let us examine this statement for a moment. Let a body be moving in the direction *a* to *b* with a speed sufficient to traverse the distance in one unit of time. Then let a force be applied to the body at *a*, at right angles to the direction of its motion, sufficient, if acting alone, to carry the body to *d* in the same unit of time. By the composition of forces, the body, at the end of the unit of time, would, therefore, be found at *c*. But the distance *ac* is greater than *ab*; and as, by the interposition of a force at right angles to its motion, the body has thus traversed a greater distance in the same time, has not its speed, as a matter of fact, been increased? and is not this increase of speed actual work? and does not this work require actual energy to perform it?



EVAN MCLENNAN.

Brooklyn, Iowa, U.S.A., June 9.

I AM glad to see my statement called in question, and hoped that it would have aroused more antagonism than has yet been expressed; because I do believe that it has important psychological or metaphysical consequences, and should therefore either be repudiated by physicists or after due discussion be accepted by non-physicists.

With regard to the special objection raised by Mr. McLennan, it may be sufficient to remark that, in his diagram, *ac* is the line of motion, *ad* the direction of the force, and that *ad* is not at right angles to *ac*. His difficulty seems to be the one that some people always feel with regard to the use of infinitesimals in general. He must remember that his diagram will not apply to the case of curvilinear motion unless the impulses contemplated are momentary and infinitesimal.

OLIVER J. LODGE.

The Scorpions at the Zoo.

YOUR contributor of the notice, published in NATURE on June 18 (p. 163), on the contents of the Insect-house at the Zoo, who laments the unfortunate circumstance that the scorpions there in captivity remain unnamed, may be glad to learn that these creatures may be easily identified, and, with a little dexterity, fearlessly handled.

During a recent visit to this house, the keeper obligingly showed me the two Egyptian scorpions, one of which—the black individual with the thick tail—was easily recognizable as *Prionurus crassicauda*, Oliv., a tolerably common North African and Syrian form.

To the other, however, I could not so readily assign a name; partly owing to its partial concealment, and partly to the fact that critical inspection is required to distinguish between the species of the genus to which it belongs. It appeared, nevertheless, to be a specimen of *Buthus europæus*, Linn., the commonest of all the Mediterranean scorpions. But my attempt to verify this point by closer examination was immediately frustrated by the keeper; who, evidently thinking that I was qualifying for incarceration in Bedlam, hastily interposed when I stretched out my hand to pick up the noxious animal.

The third scorpion I did not see; but doubtless it is a specimen of one of the species of *Euscorpius*. This, too, can be easily named, no doubt; but it will be necessary to handle the specimen in order to be certain on the point.

I would warn your contributor not to be too sanguine of the permanence of the amicable relations that appear at present to be established between these three Arthropods. If the supply of dead mice runs short, there will, of a surety, soon remain nothing but a few fragments of *Euscorpius*. Such thoroughgoing cannibals are not likely to be squeamish, when a member of another genus is before them.

In conclusion, some of your readers may be interested to know that the spider referred to as *Lycosa portosantana*—which, by the way, should be styled *Tarantula maderiana*—is a very near ally of the famous and historical Tarantula of Italy; and that the hairy Brazilian monster, the so-called Mygale, who squats under a broken flower-pot in the next cage, has no more claim to the title Tarantula than any other Arachnoid with a formidable aspect.

R. I. POCOCK.

Cetaceans in African Lakes.

WITH reference to Mr. Sclater's inquiry (NATURE, June 11, p. 124) as to the occurrence of porpoises in the Victoria Nyanza, the following extract from Bernier, who wrote about 230 years ago, will probably prove of interest.

I may add that in another passage Bernier gives further information regarding the sources of the Nile.

It would seem from the passage quoted that the occurrence of a Cetacean in the Abyssinian sources of the Nile was probably known to early travellers, and, like the occurrence of diamonds in other parts of Africa, cannot be regarded as a new discovery.

Science and Art Museum, Dublin, June 22. V. BALL.

An Armenian named Murat and a Mogul who came as ambassadors from the Christian King of Ethiopia (*i.e.* Abyssinia) to Aurungzeb shortly after his accession to the Mogul Empire, in 1659, told the French physician Bernier, who then resided at the Mogul's court, "that the Nile had its origin in the countrey of *Agaus*, that it issued out of the earth by two springs bubbling up near to one another, which did form a little lake of about 30 or 40 paces long; that, coming out of this lake, it did make a considerable river; and from space to space it received small rivers increasing it. They added that it went on circling and making as 'twere a great isle, and that afterwards it tumbled down from steep rocks into a great lake in which there were divers fruitful isles, store of crocodiles, and (*which would be remarkable enough if true*) *abundance of sea calves, that have no other vent, &c., than that by which they take in their food*, this lake being in the country of Dambea, three small days' journey from Gundar and four or five days' journey from the source of the Nile, &c., &c." ("The History of the Empire of the Mogul," English translation of 1684, p. 44).

ON SOME POINTS IN THE EARLY HISTORY OF ASTRONOMY.[1]

V.

It is imperative to be perfectly definite and clear on the question of the amplitudes above 26° at Thebes. Any amplitude within 26° means that up to that point the sun at sunrise or sunset could be observed some day or days of the year—once only in the year if the amplitude is exactly at the maximum, twice if the maximum is not reached. But in the case of these temples with greater amplitudes than 26°, it is quite clear that they can have had nothing to do with the sun. Is there, then, any additional line of evidence that the Egyptians used these temples to observe the stars? Here a very interesting question comes in; a temple built at one period to observe a star could not go on for ever serving its purpose, for the reason that the declination of the star must change by precession. Therefore a temple built with a particular amplitude to observe a particular star, useful for one period would be useless for another.

We have here possibly a means of testing whether or not any of these temples were used to observe the stars. In those very early days, 3000 or 4000 years B.C., we must assume that the people who observed the stars had not the slightest idea of these possible precessional changes; they imagined, that they were just as safe in directing a temple to a star as they were in directing a temple to the sun But with a star changing its declination in an average way, the *same* temple could not be used to observe the same star for more than 200 or 300 years; so that at the end of that time, if they still wished to observe that particular star, they must either change the axis of the old temple, or build a new one.

As a matter of fact, we find that the axes of the temples have been changed and have been freely changed; that there has been a great deal of work done on many of these temples which are not oriented to the sun, in order to give them a twist.

Once a solar temple a solar temple for thousands of years; once a star temple only *that* star temple for something like 300 years, so that the conditions were entirely changed.

We get cases in which the axis of a temple has had its direction changed, and others in which, where it has been difficult or impossible to make the change in a temple, the change of amplitude has been met by putting up a new temple altogether. We are justified in considering such temples as a series in which instead of changing the orientation of a pre-existing temple, a new temple has been built to meet the new condition of things. That, I think, is a suggestion which we are justified in making to Egyptologists on astronomical grounds.

We cannot, of course, make it with absolute certainty, for the reason that in the case of most of these temples the best Egyptologists cannot give us the most precious piece of information which we require from the astronomical point of view. That is the date of the *foundation* of the temple. If in the case of these temples it were absolutely certain that each temple was built at a certain time with a certain orientation, the use of the precessional globe would tell us at once whether or not that temple was pointed to any particular star. Some other astronomical considerations may here come to our help. If the north polar distance of a star is increasing—that is, if it is increasing its distance from the north pole—its declination is being reduced, and the orientation of the temple would be gradually becoming more and more parallel to the equator; if the declination of the star be increasing, then the orientation of the temple would have had to be more and more north or south. The change in the orientation, therefore, could give us important information, and ultimately we might be able to determine what the name of that particular star was. At present the matter must remain more or less as a suggestion; but if anything like approximate dates can be given, then astronomy really may come to the rescue of the Egyptologist and archæologist generally, and repay that debt to which I have referred, which she owes to so many other sciences.

Although, however, these matters can be discussed in a way that will indicate that the inquiry is raised, I do not wish for one moment to speak of it as being settled, because the observations which have been made already in Egypt with regard to the orientation of these temples have not been made from such a very special point of view; and further some alteration in the amplitude would be made by the presence of even a low range of hills miles away from Thebes in the case of a star rising or setting pretty nearly north or south. No one would care to make the assertion with absolute definiteness until it was known whether or not the horizon in each case was interfered with by hills or any intervening objects—was or was not one, in fact, which might be regarded as a sea horizon from the point of observation; if there were impediments, the angular height of them must, of course, be exactly known.

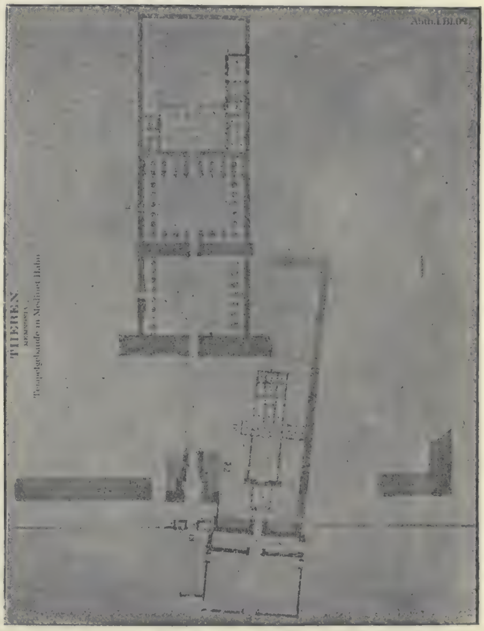

Fig. 14.—The two temples at Medinet Abou, showing the change in their orientation.

To continue this observation and this kind of thought a little further, we will go back to Karnak generally. In the first place we have the magnificent solar temple.

Next we have two parallel temples, one of them a late addition to the solar temple itself, and another one parallel to it, each of them with an amplitude of 63°, one N. of E., the other S. of W. We have then two parallel temples *at right angles* to the solar temple at Karnak. We have also a temple, with an azimuth of 68° N. of E., and one, probably older still, with an amplitude of 70° or 71° N. of E.; both these temples face northerly, and nearly in the same direction. Near the last temple we have the ruins of another one at right angles to it, and this points to the westward amplitude 19° N. of W. We may assume from the plan of the ruins that the Naos is at the east end of the temple, therefore the chief pylon would have been to the west, and therefore the axis will be in that direction. In the row of sphinxes, a double row connecting the temples of Maut and Karnak, the line is absolutely complete as far as their bases are concerned, with the exception of two where there is a gap, and that gap is exactly in the axis of this temple prolonged. Here is another instance of the rights of the line of sight of a temple being strictly preserved.

---

[1] Continued from p. 110.

The Egyptians have been accused of hating every regular figure, and even in the boundary walls of the temple of Ammon there are two obtuse angles. Round the Maut temple we also have walls, and there again this hatred of similarity seems to come out, for we have one obtuse and one acute angle. But if we examine the thing a little carefully, we find that there is a good deal of method in this apparent irregularity. The wall of the temple of Ammon is parallel to the face of the temple or at right angles to its length. One wall of Maut is perfectly parallel to the face of the temple or at right angles to the sphinxes. And the reason that we do not get right angles at one end of the wall is that the walls of the temple at Maut are parallel to the chief wall of the temple of Ammon. Surely it must be that, before these walls were built, it was understood that there was a combined worship, that they stood or fell together. One thing was not attempted in one temple and another thing in another, but the worship of each was reflected in the other. And if this be true you see that there was no hatred of symmetry, but a definite reason why these walls should be built as they were.

We can depend, and no doubt depend very completely indeed upon the labours of the Egyptologists, in the case of the temples of Rameses and of Khons. No Egyptologist so far, I believe, has ventured to tell us the date of the foundation of Karnak, but what Egyptologists have stated is that those two temples were built by the same king; their architecture is exactly similar, they are parallel to each other, and they altogether bear reference to apparently the same period of Egyptian history. Now that king was Rameses III., and the year according to Brugsch was 1200 B.C. Here then we have a definite basis of work. There is a temple with an amplitude of 63° N. of E., built 1200 B.C.; there is a temple with an amplitude of 63° S. of W., built 1200 B.C. From these amplitudes we determine as before the declinations; they come out 53° N. and 53° S.

Was there an important star with a declination of 53° N., was there another with a declination of 53° S. in the year 1200 B.C.? There *were* two important stars, one with a declination of 53° N. and another of 53° S. at that time. The north star was γ Draconis, the south star was Canopus. This strengthens the view that there was really some astronomical object in the plan and direction of these temples.

Thus, at the time when these two temples were stated to have been built, each *might have been used* to observe one the rising, the other the setting, of an important star. We have long ago seen that so far the Egyptians, like the Babylonians at a later date, only had an idea of observing a heavenly body and the position of other bodies in relation to it, so long as it was rising or setting, so that it was absolutely essential that the body which they were to observe should rise and set. You know perfectly well that in London there are many stars which neither rise nor set. The latitude of London being 51°, the elevation of the pole therefore is 51°, and from the pole to the north point of the horizon being 51°: of course any star which lies at that distance from the pole cannot set, but sweeps round without touching the horizon at all. The latitude of Thebes being 25°, the distance from the pole to the horizon is much smaller, and so the number of stars which do not rise and set is much smaller. The stars which did not rise or set were stars which were moving very slowly and the stars which rose most to the north and most to the south were those bodies which were moving most slowly while they yet rose or set. Can this slow rate of motion have had anything to do with such stars being selected for observation, the brightest star to the north, most slowly moving, the brightest star to the south most slowly moving? It is possible that observations of these stars might have been made in such a way that at the beginning of the evening the particular position of γ Draconis might have been noted with regard to the pole star, if there were no other reason; and seeing that the Egyptians thoroughly knew the length of the night and of the day in the different portions of the year, they could at once the moment they got the starting point of the rising of this star practically use the circle of the stars round the north pole as the dial of a sort of celestial clock. May not this really have been the clock with which they have been credited? However long or short the day, the star which was at first above the pole star, after it had got round so that it was on a level with it, would have gone through a quarter of its revolution.

So much then for the possible use of the temples built by Rameses III. in the year 1200 B.C. It has already been pointed out that although we have in one an amplitude of 63° N. of E. we have other temples with amplitudes of 68° N. of E. and 71° N. of E. Everybody agrees that the temple, with amplitude 63° N. of E., was built 1200 years B.C. I have shown that that temple could have observed the most northerly star which did not set. May it not have been that the 68° temple and the 71° temple were temples built to observe the same star *before* this one was built, because we know they could not have observed the star *after* this one was built, since γ Draconis was decreasing its declination, therefore in previous times its declination would have been *higher*, and the amplitude therefore of a temple to observe it would have been greater.

Looking back to the German tables and other calculations, we find that with an amplitude of 68° we get a declination of 56°, and the same tables tell us that that declination was the declination of the same star γ Draconis 2000 years B.C. It does look as if in all probability we are dealing with a series of temples not twisted but built in different places.

Can we consider that the temple with an amplitude of 71° might have been used to observe that same star long before the temples were built with amplitudes of 68° and 63°? The amplitude of 71° gives us a declination of 58°, we then find the year in which that same star γ Draconis had that declination to have been about 3000 years B.C. So that it is not impossible that temple was built first of all to observe γ Draconis 3000 years B.C., that after a time the star changed its declination so much that another temple became necessary, and 1000 years afterwards the change again became large, and still another temple was built to observe it. The three temples may form one series.

The discussion is a little difficult because the orientation is very far towards the south and north, and therefore a hill a few miles off would make a difference of 2° or 3° in the orientation of the temple, and as yet we have no observations that throw light on this point.

We have then at Thebes alone three converging lines of evidence which all go to strengthen the view that these temples were really—whatever else they might have been—usable as solar and stellar observatories. The difference being of course that in the case of the solar temple no large change of amplitude was necessary, but that in the case of every stellar temple after a lapse of a certain number of years depending upon the position of the star, the temple must be twisted round if it were wished to continue to make observations of the same star.

That raises an interesting question by the way. Long after the temple had been used for observation of a particular star, long after that temple line was blocked by extended building, if the horizon of these temples was left open it looks very much as if when another bright star came along it was laid hold of for a new set of observations. However that may be, it is rendered extremely probable, by the considerations I have brought before you, that the Egyptians 3000 years B.C. had been rendered practically conversant with the result of the precession of the equinoxes by the fact that they had to rebuild and alter their temples from time to time because the stars changed their declination. If that be confirmed by subsequent investigations, it will show that these Egyptians possessed a very much more profound knowledge of astronomy than they have received credit for, because it is stated that the precession of the equinoxes was discovered by Hipparchus. It looks as if the precession of the equinoxes was probably published by Hipparchus as the result of an examination of the untold wealth of Egyptian astronomical observations which has been unfortunately lost to the world.

This question of orientation is after all one which survives among ourselves. All our churches are more or less oriented, which is a remnant of old sun worship, and the church is not always oriented exactly to the east, but so that the light of the sunrising upon the Saint's day to whom the church is dedicated may be thrown along the chancel.

It has long been known that Stonehenge is oriented to the rising of the sun at the summer solstice. Its amplitude instead of being 26° is 40°; with a latitude of 51°, the 26° azimuth of Thebes is represented by an azimuth of 40° at Stonehenge.

The first of January is very near the winter solstice, but is not quite the winter solstice. If you look up the old records of the races that lived 2000 or 3000 years B.C., you will find that the different races began their year at different times, and even that the same race at different times began their year differently; the choice lay among the equinoxes and the solstices, and seeing that one of the very oldest temples at Thebes is oriented to sunset at the summer solstice we should not be at all surprised if investigation shows that when that temple was built more than 3000 years B.C., the Egyptian year really began in what we should call our summer. We have ample evidence of this. And I think there is little doubt that when Stonehenge was built it certainly was built by people who began their year with the summer solstice, which you will remember is the time of the year in which in many countries it is the habit still to light fires upon hills and so on.

The next point is, what was probably the use made of these temples besides determining the length of the year and regulating so far as they could the seasonal changes, the times of the solstices, the times of the equinoxes, and the various celestial phenomena?

We understand that in the very beginning of observations in all countries, the moment man began to observe anything, we saw that he began to observe the stars, and the moment men began to talk about anything they had seen they must have started by in some way or other defining the particular stars they meant.

They would obviously talk first of the brightest stars, and separate them from the dimmest ones; they would then discuss the stars which never set, and separate them from those which did rise and set; then they would take the most striking configurations, whether large or small; they would choose out the constellation of Orion or the Great Bear, and for small groups the Pleiades. These would attract attention, and be named before anything else. Then later on it would be imperative in order to connect their solar with their stellar observations that they should name the stars which lay along the sun's path in the heavens. They would confine their attention to a belt round the equator rather than consider the configuration of stars half-way between the equator and north pole. In all countries—India, China, Babylonia, Chaldæa, Egypt—they had a sort of girdle round the heavens, called by different names in different countries, and the use of this girdle of stars, which sometimes consisted of twenty-eight stations, sometimes of twenty-seven, and sometimes of only ten, was to enable them to define the place of the moon or of any of the planets in relation to any of these stars. That condition of things, that stage of thought, is brought well before us in the Jewish Scriptures.

In the Book of Job we read, "Canst thou bind the sweet influences of Pleiades, or loose the bands of Orion? Canst thou bring forth Mazzaroth in his season? or canst thou guide Arcturus with his sons?"

Here we have the difficulty which has met everybody in going back into these old records, because there was no absolute necessity for a common language at the time; it was open to everyone to call the stars any name they chose in any country, therefore it is difficult for scholars to find out what particular stars or constellations were meant by any particular words. In the revised version, Arcturus has given place to the Bear with its train, and even our most distinguished scholars do not know what Mazzaroth means. I wrote to Prof. Robertson Smith the other day to ask him to give us the benefit of his great knowledge, and he says that Mazzaroth is probably that band of stars round the ecliptic or round the equator to which I have referred, but he will only commit himself to the statement that it is a probable enough conjecture; other people believe that it was a reference to the Milky Way.

I mention this to show you how very difficult this inquiry really is. The "seven stars" undoubtedly mean the Pleiades and not the Great Bear. Among the brighter stars, Arcturus, the Pleiades, &c., are referred to by Homer and still earlier writers. So far as Egyptian and Chinese astronomy goes, practically the first reference to a constellation appears in Egypt with reference to the equinox which happened 3285 years B.C., and in China with reference to the Pleiades in the equinox of 2357 B.C.

In observing stars nowadays, we use a transit circle which is carried round by the earth so as to pick up the stars in different circles round the axis of the earth prolonged, and by altering the inclination of the telescope of this instrument we can first get a circle of one declination and then a circle of another.

The Egyptians did not usually employ meridian observations. Did the Egyptians make star maps? They certainly did. In the temple of Denderah, which is a comparatively modern temple, there is a very precious series of records which is certainly not at all modern. It represents a good many of the Egyptian constellations. The central part was in all probability the zenith point of Denderah itself, and at a certain distance from the centre point we have the zodiac represented excentrically. The constellations round the edge are those nearest the horizon; the central ones are those nearest the north pole; instead of having the Great Bear, we have the constellation of the Thigh, representing the well-known seven stars; in addition we have the constellation Hippopotamus, which has now entirely disappeared. There is also a Babylonian zodiac, which will show you that, although Babylonia and Egypt were adjacent countries, yet that they had a perfectly different set of constellations. Our present constellations came not from Egyptian times, but from much later—from Greek times. It is almost impossible to hope to recover the names of the constellations used by people earlier than the Greeks, but still much is to be hoped from the study of the Babylonian records. In these we have a snail being drawn along by the tail of a snake or dragon. It is quite possible that we may have there the origin of our constellation Draco, which is the northern constellation, and it is quite possible that this snail may indicate that the stars in it moved with very great slowness. But it is impossible at present to co-ordinate these different fancies together.

A very important paper has recently been published by Mr. Le Page Renouf suggesting that before the year 1500 B.C. the Egyptians really had an idea of meridional observations. These observations are recorded in several manuscripts found in tombs; they seem to have been given as a sort of charm to the people who were buried in order to enable them to get through the difficulties of the way in the nether world.

The hieroglyphs state that a particular star of a particular Egyptian constellation is seen at a particular hour of the night; we have twelve lines representing the twelve hours of the night, and it is stated that we have in these vertical lines the equivalent of the lines in our transit instruments, and that the reference "in the middle," "over the right eye," "over the right shoulder," or "over the left ear," as the case may be, is simply a reference to the position of the star.

If this should be confirmed, one of the remarkable things about the inquiry will be that the Egyptians did not hesitate to make a constellation cover very nearly 90°. In those days evidently they wished to have as few constellations including as many stars as possible, in order perhaps that things might be more easily remembered.

When the zodiac of Denderah was mentioned, I pointed out the constellation of the Hippopotamus very near the north pole. This constellation is referred to in the records in question.

Such then are some of the ideas which are suggested by the recent work of the Egyptologists. You see, I trust, that it is important that this work should be continued as closely associated as possible with astronomical ideas, because, merely taking a very small part of the area of which they have begun the consideration, we have come to the conclusion that, dealing with the temples alone, there seems a very high probability that 3000, and possibly 4000 B.C. the Egyptians had among them men with some knowledge of astronomy, and that 6000 years ago the course of the sun through the year was practically very well known, and methods had been invented by means of which it might in time be better known, and that not very long after that they not only considered questions relating to the sun, but began to take up other questions relating to the positions and the movements of the stars. It is quite probable that 1500 years B.C. at least they had an idea of meridional observations. If this be so, and if more and more can be proved, I think you will agree that, as I said before, astronomy will have a slight opportunity of repaying some of the great debt which she owes to the other sciences.

J. NORMAN LOCKYER.

THE LATER LARVAL DEVELOPMENT OF AMPHIOXUS.

THE memoir by Mr. Arthur Willey, B.Sc., of University College, London, on this subject, in the *Quart. Journ. Microsc. Science*, March 1891, deserves more than a passing notice. It is one of the most important contributions which have been made to a knowledge of this very interesting animal. In the summer of 1889, Mr. Willey was sent by Prof. Ray Lankester with the aid of a Government grant to collect the larvæ and embryos of Amphioxus at Faro, near Messina. He returned with a large series, and in the winter 1889–90 worked out in the laboratory of University College, chiefly by means of sections, the history of the formation of the atrial cavity in this animal. In a paper published jointly by Prof. Lankester and Mr. Willey (*Quart. Journ. Micr. Sci.*, August 1890), it was shown that the atrial cavity does not form, as supposed by Kowalewsky and by Rolph, as the result of a down-growth of lateral epipleura; but that it forms as a longitudinal groove which sinks inwards along the ventral surface, becoming floored in by a small horizontal growth on each side corresponding merely to that portion of the adult animal's ventral surface which lies between the two metapleura. The groove, now become a narrow tube, expands right and left, until it acquires the proportions of the adult atrial chamber.

The preserved material brought home by Mr. Willey in 1889 did not enable the observers to determine the mode of origin of the second row of gill-slits. Stages were noted in which there were as many as fourteen gill-slits of the first series (which are placed anteriorly on the animal's right side), and stages were observed, of no greater size, in which two rows of gill-slits were present—one series on the right side and one on the left side of the pharynx; whilst the mouth, which in the specimens with a single series was completely lateral (on the left side), had now taken up a median position.

Mr. Willey again visited Faro in the summer of 1890, for the purpose of determining, by the study of living transparent larvæ, exactly the mode of origin of the second row of slits, and the steps in the "symmetrization" of the larva. The brief account and few unconvincing figures given by Kowalewsky, in 1866, in relation to this matter had not commanded general confidence, although it was felt that so accurate and accomplished an observer could not have been completely mistaken. Balfour had said, in reference to Kowalewsky's observations on this matter, that he was "tempted to suppose that his observations were made on pathological specimens."

Mr. Willey completely and most successfully accomplished the object which he set before himself in his second visit to Faro, and the results obtained are given in the paper under notice, illustrated by three folding-plates. He confirmed the main feature of Kowalewsky's observations, viz. that the first row of gill-slits, after having (so far as the first eight are concerned) taken up a position on the *right* side of the pharynx, rotate downwards across the median ventral line, and rise up into position on the *left* side, whilst, simultaneously, a new series appears on the right side, not one by one, but as many as six being formed at approximately the same moment. Mr. Willey corrects Kowalewsky's brief account in one or two numerical details, and adds some very important facts, which are quite new. He shows: (*a*) that the anteriormost slit of the primary series closes up and disappears during the process of rotation; (*b*) that some of the hinder slits of this series, which are not far advanced when the rotation begins (there being usually fourteen, of which the last six are very small, and lie in the median ventral line), also close up; so that, when the rotation is complete, and the second series of gill-slits has advanced in development to the number of eight, a "critical phase" is reached in which there are only *eight* gill-slits on each side of the pharynx, all fairly well developed. From this time forward new gill-slits are formed on each side behind the last formed, and continue to increase in number so long as growth continues, which appears to be as long as the Amphioxus lives.

But the most important discovery made by Mr. Willey is as to the origin of the endostyle, a structure which has great importance from the fact that it can be clearly identified, on account of its minute histological structure, with the endostyle of the Ascidians.

In the anterior region of the buccal cavity, previous observers have described in very young Amphioxus larvæ (with only one gill-slit) an elongated gland; "the club-shaped gland." It opens to the exterior on the left side, just in front of the big laterally-placed mouth, whence it can be traced, bending down across the median line and passing up at *right angles* to the long axis of the body along the deep surface of the right wall of the buccal cavity. It opens at its apex, as Mr. Willey has shown, into the buccal cavity. Its earliest appearance (as described by Hatschek) resembles that of a gill-slit, though it precedes both the mouth and the first gill-slit in date. Mr. Willey suggests that it is a modified gill-slit. By the side of this club-shaped gland and in front of it, immediately associated with it, is a band-like tract of modified intra-buccal epithelium. When there are about eight gill-slits of the primary series present, it is noticeable that the apex of the club-shaped gland is bent over, so that the gland tends to become <-shaped, with the angle directed backwards; the adjoining epithelial tract faithfully follows the bend. At first the upper limb of the < is a good deal smaller than the lower, but as the primary series of gill-slits move from the right side of the pharynx to the left, the two limbs of the < become nearly equal in length, and the angle takes up a position between the primary and the new secondary series of slits. The club-shaped gland-tube now atrophies entirely, but the <-shaped epithelial tract does not; it grows rapidly at its angle along the line or interspace between the two series of slits, forming a double tract of modified epithelium consisting of parallel extensions of the two limbs of the <. It is now the epithelium of the hypopharyngeal ridge or endostyle.

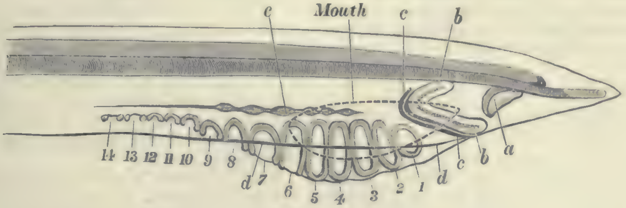

Fig. 1.

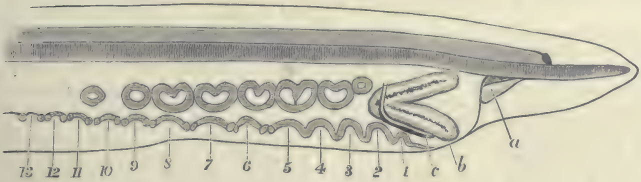

[Fig. 2.

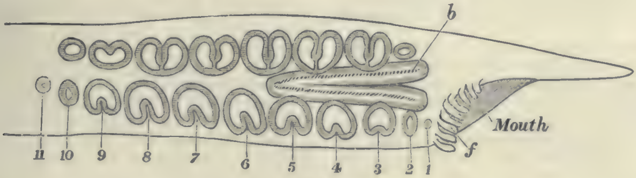

Fig. 3.

Figs. 1, 2, 3.—Diagrams showing three stages in the development of the gill-slits and endostyle of Amphioxus. Figs. 1 and 2 are seen from the right side; Fig 3 from the ventral aspect. In Fig. 1 the position and shape of the mouth, which lies on the left side of the animal, are indicated by a dotted oval. The primary series of gill-slits are numbered in all the figures. The secondary series are not numbered. Fig. 2 shows the rotation downwards of the primary series of gill-slits and their nearly complete disappearance from view on the right side; at the same time the secondary series have developed to the number of eight, and the endostyle has become <-shaped, and is pushing its angle between the two rows of gill-slits. Fig. 3 shows the atrophy of the most anterior primary gill-slit, whilst some of the hindermost have disappeared and numbers 10 and 11 are in course of closure and disappearance. *a*, præoral ciliated pit, opening on the animal's left side, but seen through the transparent integument; *b*, the endostyle (<-shaped tract of modified epithelium); *c*, the club-shaped gland; *d*, the edge of the right meta-pleur (the atrial cavity is not yet formed in the anterior pharyngeal region); *e*, the six thickenings which develop the six anterior gill-slits of the secondary (permanent right-side) series; *f*, the præoral tentacles.

Mr. Willey regards the club-shaped gland so intimately associated with the first stages of the endostyle as a modified gill-slit belonging to the secondary (the permanent right-side series). Its early development in *front* of the mouth indicates this; since, when the mouth acquires a median position (passing from the left towards the right by a relative growth, the reverse of that which brings the primary gill slits from the right to the left!), structures just in front of it would be thrown round to the right side, the side of the secondary series of slits. He suggests that it is the early-developed anterior member of the secondary series of gill-slits; and points out that just as this modified gill-slit atrophies, so does its pair in the primary series, viz. the first.

Mr. Willey points out the possible importance of these facts in reference to the views of Dohrn and of Van Beneden, and makes an interesting comparison between the Ascidian tadpole and the Amphioxus larva, with a view to suggesting some explanation of the extraordinary asymmetry of the latter. Mr. Willey thinks that a cause of the one-sided position of the mouth and of the primary series of gill-slits in the Amphioxus larva may be found in the excessive anterior prolongation of the notochord at an early period of development, necessitating a pushing to either one side or the other of the mouth. There appears to be nothing in the mode of life of the larva—a free-swimming ciliated creature—which can be correlated with its asymmetry. The gradual process of "symmetrization," by which the Amphioxus establishes more or less completely a bilateral symmetry on its way to the adult form, is exactly the converse of that process by which the symmetrical larva of the Pleuronectid fishes becomes one-sided; but in the latter case the asymmetry is clearly correlated with a peculiar life on the sea bottom, whilst in the former case we can discover no such relation to environment. E. R. L.

THE CARDIFF MEETING OF THE BRITISH ASSOCIATION.

TO arrange for the reception of the members of the British Association who will visit Cardiff in August next, an influential Local Committee has been formed, with the Most Honourable the Marquis of Bute, K.T., Mayor of Cardiff, as Chairman, and a substantial sum has been subscribed for the purpose of defraying the cost of the meeting.

Several sub-committees have been formed, all of which report to the Executive Committee, to which also the Council of the British Association has assigned the duty of electing new members and associates. Up to the present time 7 life members have been added, and over 200 annual members and associates, and as the time for the meeting approaches the number of new members and associates will be largely increased.

It may be convenient to describe what has been done by the sub-committees, so as to give a systematic account of the preparations already made and in progress to provide for the comfort and entertainment of our expected visitors.

(1) *Hospitality and Lodgings.*—Many of the principal residents in Cardiff and the neighbourhood have signified to the Committee their desire to entertain members of the Association, and as the date of the meeting draws nearer numerous additional offers will be made by those of the townsmen who are unwilling or unable to fix their engagements so long beforehand. It is understood that those ladies and gentlemen who have offered to invite guests will send out invitations as soon as it is known to the Committee who are coming.

The hotel and lodging accommodation is not so great as in some other towns, but the Committee feel sure that with the private hospitality which will be offered there will be enough for the needs of our visitors. The list of hotels and lodgings will be ready for distribution about the middle of July, it having been delayed to make the list as complete as possible. The list will be accompanied by a map of Cardiff taken from the most recently executed ones.

(2) *Reception and Section Rooms.*—The reception room will be at the Town Hall, practically the whole of which has been placed at the disposal of the Local Committee for the use of the Association. The vestibule will be devoted to the sale of tickets, the distribution of programmes, and other information, whilst the Assembly Rooms will be fitted up as a drawing-room with writing-tables, post-office facilities, and a book-stall. The Council, Committee of Recommendations, and General Committee will meet in various rooms, and others will be set apart for the officers of the Association.

As the Town Hall is about half a mile from the Section room furthest away, a portion of the Drill Hall, the use of which has been kindly granted by Lord Bute, Colonel Gaskell, and Colonel Page, will be fitted up as a drawing-room, and the remainder will be used as a luncheon-room. As the Drill Hall is situated within very easy distance of almost all the Section rooms, the members of the Association will doubtless appreciate the advantage of having a drawing-room and dining-room so close at hand.

The majority of the Section rooms are very close together, and the greatest distance is not more than half a mile; tramcars and busses, however, run frequently between the extreme points, so that even that distance should offer no difficulty in the way of members wishing to attend different Sections.

(3) *Entertainments.*—The usual *conversazioni* will be given on Thursday, August 20, and on Tuesday, the 25th, and it is hoped that scientific men will aid the Committee in contributing towards the entertainment of our guests by the exhibition of novel experiments or specimens. The Park Hall, in which the *conversazioni* will be held, is well suited to this purpose, and it is the desire of the Committee to introduce as many scientific novelties as possible.

A garden party, to which all members of the Association will be invited, will be given by Lord and Lady Bute, probably on the Friday afternoon, though the date may be subject to alteration. Other social entertainments are projected by Lord Windsor and others, and Cardiff will probably in this respect not fall behind what the members have been accustomed to at other places of meeting.

(4) *Excursions.*—A considerable variety of excursions has been provided for both the Saturday and the following Thursday. For the former, arrangements are being made by Sir W. T. Lewis for a party of members to visit the Cardiff Docks; by a committee appointed by the Board of Directors to visit the Barry Docks; by the Mayor of Newport and the Chamber of Commerce for a party to visit Newport and Caerleon. A special excursion is being arranged by the Colonel commanding the Severn Valley division of submarine miners for officers of the British Army to inspect the Severn Valley defences. The steamer will land the officers at the steep and flat holmes, and will continue with the civilians on board to Weston, from which they will visit Worlebury Hill and camp.

Other excursions will be of geological and archæological interest, and will include excursions to Penarth and Lavernock, where the finest section of Rhætic beds in England is exposed; to the interesting dolmens at St. Nicholas and St. Lythan's; to Llantwit-major, where a year or two ago the remains of a Roman villa were unearthed, and where a college is said to have existed in the fourth century; to Tintern Abbey and Raglan Castle, the Forest of Dean, Merthyr, Brecon, and to some of the numerous collieries and iron-works in the South Wales coal-field. A practical natural history excursion is being organized by the Cardiff Naturalists' Society to the Vale of Neath, which from the beauty of the spot should prove attractive. Several owners of works in the neighbourhood of Cardiff have expressed their willingness to throw them open to the members, and arrangements will be made for visits to some of them.

(5) *Publications.*—A guide-book to Cardiff is being prepared for distribution to all members and associates, and the descriptive articles have been intrusted to the gentlemen who were best fitted to write them. The article on the history and archæology of Glamorganshire has been written by the veteran G. T. Clark, of Dowlais, whilst that on the topography of Cardiff was undertaken by the late James A. Corbett, who, unfortunately, died before it was quite complete. Mr. T. Forster Brown, President of Section G, has undertaken the description of the mining, geological, and statistical features of the district; the industrial portion being in the hands of Mr.

Galloway. The geological, zoological, and botanical descriptions have been written by Mr. T. H. Thomas and Prof. W. N. Parker, with the help of many others. The account of the educational arrangements of Cardiff will be treated of by Mr. Whitmell, Inspector of Schools, and Principal J. V. Jones.

The excursions hand-book will contain a map, on a scale of four miles to the inch, of the whole of the district in which the excursions will be held, specially prepared for the Committee by Messrs. Bartholomew and Co., Edinburgh. As detailed accounts as possible of the various points to be seen in the excursions will be given by those having special knowledge: taken together with the guide-book, it is thought that a very complete description of everything connected with this portion of South Wales will be furnished to the visitors.

Other Committees have been formed for the evening lectures and the working men's lecture, but little more can be said about them than that they will provide to the fullest extent for the wants of the Association. The Local Committee are anxious that this shall be the case in every particular, so that the first visit to the metropolis of Wales will not suffer in comparison with previous meetings of the Association. R. W. ATKINSON.

MARINE BIOLOGICAL ASSOCIATION OF THE UNITED KINGDOM.

WE have received the annual report of the Council of this Association, presented at the general meeting on June 24—the President, Prof. Ray Lankester, F.R.S., in the chair. In the sea, as well as on land, the severe winter appears to have had a marked effect on the fauna, and there is also a complaint of mortality in the aquarium attached to the Laboratory during the colder months; a result perhaps somewhat unexpected, considering the comparatively high winter temperature of the sea. We are glad to learn that a self-sown fauna is springing up in the tanks, the condition of which is said to be steadily improving, as is the case with all aquaria after one or two years of use.

Under the head of the library (which ought to be represented in the balance-sheet by a larger sum than is at present debited to it) the Association is to be congratulated on having received the gift of the late Mr. Spence Bate's library, constituting an exceedingly valuable collection of the literature of Crustacea.

Some of the changes made in the permanent staff have been chronicled already: Mr. Calderwood has replaced Mr. Bourne as Director, and has appointed Mr. H. N. Dickson to succeed Mr. Garstang, who took up a Fellowship at the Owens College in December last. Two temporary members have been added to the staff: Mr. F. Hughes, to carry out from the chemical point of view an inquiry into the possibility of manufacturing an artificial bait; Mr. E. W. L. Holt, known already as the author of some papers on Teleostean development, to conduct investigations into the immature fish question as regards the Dogger Bank and the region eastwards of it—the lines of this latter inquiry are sketched in an appendix to the report. Among the fishery investigations of the past year are quoted experiments on the rate of growth and the age of sexual maturity in food-fish, oyster and lobster culture, and the anchovy fishery which the Association desires to initiate. We are glad to see that systematic physical observations are to be taken at the Laboratory in future.

Eleven gentlemen have visited the Laboratory during the year for the purposes of research, some of them on more than one occasion. This number, however, is by no means as large as it should be.

The balance-sheet shows a satisfactory, if small, increase in receipts, the items pointing to an increased use of the Laboratory, both for research and for the purchase of material for teaching purposes. A sum of £500 (in addition to the annual grant of £500) has been placed on the Civil Service estimates for the current year, which will, if passed, place the Association in a position to carry on its work with less difficulty than has hitherto been the case.

UNIVERSITY EXTENSION STUDENTS AT CAMBRIDGE.

THE work done by University Extension students at Cambridge last year was so satisfactory that the Syndicate for local lectures are encouraged to repeat the experiment this year. They will be prepared to receive a larger number of students, say from 60 to 80, most of whom will be lodged either at Selwyn College or at Newnham College. The period of study will last from July 28 to August 22, or nearly a month in all. The Syndicate have just issued a detailed programme of the various courses of study; and we are glad to see that due attention has been paid to the claims of science as well as to those of literature and art. At the chemical laboratory, on alternate days, there will be a course of demonstrations illustrating the methods of chemical manipulation in a short series of typical experiments. The pupils will be first shown each experiment, and will then be expected to repeat it for themselves. At the Cavendish Laboratory, on alternate days, a course of short experimental lectures, chiefly on electricity and magnetism, will be delivered; and most of the experiments shown in the lectures will afterwards be performed by the students for themselves. Geology will be studied, on alternate days, at the Woodwardian Museum, where there will be a course of demonstrations on the leading fossil types of the animal kingdom, from the specimens in the Museum. A course of demonstrations, followed by practical work, will be given, on alternate days, in the physiological laboratory; and Mr. Graham, chief assistant at the Observatory, will receive students and explain the uses of astronomical instruments. Arrangements will also be made for taking small parties of students to the Observatory at night. Single lectures will be delivered by various eminent Cambridge men, and in this part of the work science will be represented by Prof. G. H. Darwin, who will lecture on the history of the moon or some allied subject. We may note that the students in science will be allowed to read in the Philosophical Library.

NORMAN R. POGSON, C.I.E.

WE regret to have to announce the death of Mr. Norman Pogson, for thirty years the Director of the Observatory at Madras. Mr. Pogson has been so long absent from England that, in a sense, he may be said to have outlived his reputation; but those who can recall the condition of astronomy in this country some thirty years since will remember him as a rising astronomer of considerable promise, and as one of the most indefatigable observers at that time. If his subsequent career has not entirely fulfilled his early promise, perhaps the condition of the Madras Observatory is to some extent the cause. We believe that its astronomical equipment is very old and inadequate, and possibly Mr. Pogson has accomplished all that could be done with his instruments and his staff.

Mr. Pogson's astronomical career commenced at Mr. Bishop's Observatory in Regent's Park, at that time under the direction of Mr. J. R. Hind, and he there took part in the observations for forming the ecliptic charts published from that Observatory. In 1851 he left London to assume an assistantship in the Radcliffe Observatory, Oxford, under the late Mr. Johnson; and there his zeal was rewarded by the discovery of several minor planets, in days when the number of the known asteroids was comparatively small, and their discovery conferred some little distinction upon their fortunate discoverer. Of greater importance to astronomy was his subsequent devotion to variable stars and photometry, the latter carried out, we believe, with the apparently inappropriate instrumental means of the heliometer of the Radcliffe Observatory, Oxford. But the result of his investigation of the amount of light that separates two consecutive magnitudes has never been displaced, and the fortunate employment of the number, whose logarithm is 0·4, to express this ratio will probably long connect Mr. Pogson's name with the history of accurate photometry.

After a somewhat short stay at the Hartwell Observatory, Mr. Pogson left England in 1861 to take charge of the Madras Observatory. His direction of that institution will always be remembered in connection with the extraordinary discovery of a telescopic comet, effected in consequence of the telegraphic communication he received from Prof. Klinkerfues, who expected that Biela's comet might be seen in the constellation Centaur, after the brilliant meteoric shower to which that comet had given rise in November 1872. Mr. Pogson looked in the direction indicated, and by a remarkable coincidence found a comet, which he observed on two, and only two, occasions. The orbit remains, therefore, indeterminate, but there is good reason to believe that the object seen was in no way connected with either of the two condensations which together make up the lost comet of Biela. And thus another and not uninteresting chapter was added to the history of this comet. Several volumes of observations have been published under Mr. Pogson's direction; the last bears the date of 1870, so that probably, and as the Director has often lamented, the reductions are considerably in arrear.

It will be interesting to watch the future of this Observatory. It is to be hoped that some steps will be taken to place it more in accordance with the requirements of the present time. We believe that its abandonment has even been canvassed, but it cannot be sufficiently regretted if an Observatory, possessing as that does many historical associations, and occupying a very favourable position on the earth's surface, be allowed to disappear.

W. E. P.

NOTES.

The death of Wilhelm Weber, the illustrious physicist, is announced. He died at Göttingen on June 23. On a future occasion we shall give some account of his services to science.

The second lecture in connection with the Faraday Centenary was delivered by Prof. Dewar, F.R.S., at the Royal Institution on Friday evening last.

On Tuesday, Lord Cranbrook, in the House of Lords, moved the second reading of a Bill the object of which is to allow the managers of science and art schools to transfer them to local authorities when they desire to do so. Lord Cranbrook explained that at present there were considerable difficulties in the way, and that the process was a very long and tedious one. The Bill proposed to make these schools transferable in the same way as ordinary schools could be transferred to School Boards. The Bill was read a second time.

Drs. J. Bornmüller and P. Sintenis propose to occupy the present summer with an investigation of the flora of the islands Samothrace and Thasos, from which very few collections are to be found in European herbaria; also of Mount Athos and of the Bithynian Olympus. They then intend to take up their winter quarters in Mossul, and to spend the following spring and early summer in the comparatively unknown mountainous region of Djebel Hamzin near Bagdad, and the mountains to the north and east of Mossul.

The distinguished Italian botanist, Prof. O. Penzig, is about to start on a botanical expedition to Massowah and Bogos.

Mr. J. T. Nicolson, at present Prof. Ewing's demonstrator in the University of Cambridge, has been appointed to the Chair of Mechanical Engineering in the McGill University, Montreal.

A stall for the sale of "zoological photographs" has just been opened in the Zoological Society's Gardens. It is placed in the centre of the Gardens, near the band-stand, and has an attractive exterior. The photographs sold are mostly representations of animals in the Society's Gardens, but also include some taken in the Jardin d'Acclimatation of Paris, and in other similar establishments.

The marine laboratory of the Johns Hopkins University will be open this summer at Port Antonio on the north-east coast of Jamaica. According to *Science* of June 19, Prof. Brooks and some members of his party had already started for the station.

There has been lately formed in Berlin (we learn from *Naturw. Rdsch.*) a "Union of friends of Astronomy and Cosmical Physics," with the view of organizing practical co-operation in these subjects of research in Germany, Austria, Hungary, Switzerland, and neighbouring countries, and also in the colonies, and where membership may be desired. The object is to be sought by means of free communications of the members or groups of members to head-quarters, whence advice and results of observations, &c., will be issued. Sections are formed for observations (1) of the sun; (2) of the moon; (3) of the intensity and colour of starlight and of the Milky Way; (4) of the zodiacal light and meteors; (5) of polar light, terrestrial magnetism, earth currents, and atmospheric electricity; and (6) of clouds, halos, and thunderstorms. Prof. Lehman-Filhés has been elected President of the Union, and the presidents of the sections are Förster, M. W. Meyer, Plassmann, Jesse, Weinstein, and Reimann.

According to a telegram sent through Reuter's Agency from San Francisco on June 29, a series of sudden sharp earthquake shocks, accompanied by subterranean rumblings, passed through San José, California, that morning. The first shock was so violent that the electric-light tower, two hundred and forty feet high, swayed for at least ten feet. A panic prevailed in the town; and in two of the principal hotels, which were filled with tourists from the East, men and women rushed half-dressed from their rooms into the corridors in a great state of alarm. The city rocked like a ship in the trough of the sea, and when the second shock occurred, buildings rose and fell with a slow undulating motion, one partly erected brick building tumbling to the ground. Many chimneys fell, and a large number of windows were broken, while considerable damage was done to crockery and other fragile articles in the houses.

Germany had very heavy rains on November 22 to 24 last year, causing floods at a rather unusual time in the region of the Elbe, Weser, &c. It is shown by Prof. Hellmann, that Middle and West Germany were then on the front side of a deep depression, which passed very slowly from north to south, taking about 90 hours from the North Sea to Central Germany, less than half the usual speed from west to east. A region of high pressure with cold lay to the east, blocking the course in that direction, and this afterwards spread over the flooded country, covering it with ice.

THE Central Meteorological Observatory at Tokio, Japan, has begun the publication of hourly meteorological observations, commencing with January 1890. The observations are contained in monthly Bulletins, and include all the usual elements, together with vapour tension, humidity, earth temperature, bright sunshine, and hourly and daily means. Meteorological observations have been made for some years in various parts of Japan, including hourly observations at Tokio since January 1, 1886, but have hitherto only been published for certain hours. The observations are all made without self-recording instruments, excepting those of wind and sunshine. Some years ago the Director of the Service, I. Arai, visited this country, and other European countries, for the purpose of studying the various meteorological organizations, and we have no doubt that this important publication will be very valuable for meteorological researches referring to the North Pacific Ocean, where information is comparatively scanty.

M. MASPERO has an interesting article in the current number of *La Nature* on the dog in ancient Egypt. It is illustrated by representations of dogs reproduced from Egyptian monuments, and by a mummy of a dog recently opened and sketched by M. Beckmann. In ancient Egypt, as in modern Europe, the dog was regarded both as a friend and as a useful servant. He also received the honours of a god, and there are cemeteries of dogs (corresponding to the cemeteries of cats) where mummies have been found by the thousand. Attempts have been made to identify the various species of dogs represented in wall paintings, but those naturalists who have investigated the subject have not always arrived at the same conclusions. M. Maspero points out that mummies supply more trustworthy materials for study, and urges that men of science should lose no time in examining some of them, as cemeteries of animals are being very rapidly "exploited."

A COMMERCIAL company has for some time been working quarries in the neighbourhood of the well-known glacial grooves at Kelley Island, Ohio; and it was feared that these remarkable relics of the glacial epoch might be wholly destroyed. Fortunately the president of the company understands the interest of the phenomena, and has taken care to prevent the most striking of them from being injured. We learn from the Cleveland *Leader* that some of the grooves have now been rendered safe, the company at its recent annual meeting having decided that the rocks on which they are furrowed should be made over to the president, by whom they will be transferred to a scientific or historical society, "to be preserved in perpetuity for the benefit of science."

MR. C. DAVIES SHERBORN is, we are glad to find, making satisfactory progress with the stupendous task he has undertaken in the production of his "Index Generum et Specierum Animalium." Mr. Sherborn has found it absolutely necessary to accept the year 1758, the date of the tenth edition of Linnæus's "Systema," instead of the twelfth edition (1766), as the starting-point of binomial nomenclature in zoology, and this decision was greatly strengthened by the advice of Prof. Sven Loven, Dr. D. Sharp, and others who had carefully studied the question. This is the only alteration which has been made in the original scheme (see NATURE, vol. xlii. p. 54). During the year, five hundred volumes have been worked through, page by page, and a total of forty thousand species have been recorded, *in duplicate*, involving a use of 80,000 slips. Each species is recorded on a separate slip (5 inches × 2¼), the whole of the *reference*, with the sole exception of the page, being printed with india-rubber type, thus insuring perfect accuracy of date and parts of volumes: as the pages are also checked during work, the chances of misquotation are reduced to a minimum. As the volumes mentioned include the whole of the publications of Linnæus, many of Fabricius, Thunberg, and other voluminous authors of that early period, it is, perhaps, permissible to think that more rapid progress may be made in future years. The dates of publication of the separate parts of a work have been carefully attended to, and much valuable information has been obtained. Some of this has appeared in the *Annals of Natural History* (Pallas's "Icones Insect.," "Nov. Spec. Quad.," and White's "Journal"), while much remains in manuscript until the final completion of detail admits of its publication. As is well known, the authorities of the Natural History Museum have rendered every facility to Mr. Sherborn for the prosecution of his work, and the storage of the manuscripts within the walls of that institution, reducing the risk of loss by fire to a minimum, is a concession highly valued by the author. One set of the slips is arranged in order of genera, and, on application, is available for reference to anyone compiling a monograph of a genus. The manuscript is frequently consulted by those working at the Natural History Museum, even in its present imperfect state, and will, from the very nature of the method of recording, prove of increasing value as it grows to larger proportions.

IN the report of the trustees of the South African Museum for 1890 it is stated that the curator, Mr. R. Trimen, has completed a thorough rearrangement of the fine collection of South African Diurnal Lepidoptera in accordance with the monograph of those insects recently published by him, incorporating many additional species, and replacing imperfect or worn examples by fresher and more characteristic specimens. He has also begun the rearrangement of the more numerous and less known Crepuscular and Nocturnal Lepidoptera. Mr. Trimen has completed for publication two papers—one on the very interesting series of butterflies collected in South-West Tropical Africa by Mr. A. W. Eriksson, and presented by that explorer to the Museum in 1888; and the other on some additions to the list of extra-tropical South African butterflies since the publication of the concluding volume of his work.

AN interesting account of the nest and eggs of the cat-bird (*Ailurœdus viridis*, Latham) is given by Mr. A. J. North in the latest number of the Records of the Australian Museum (vol. i., No. 6). The habitat of the cat-bird is the dense scrubs of the coastal ranges of New South Wales. Although the bird is common, authentic specimens of its nest and eggs seem to have been unknown until lately. For an opportunity of examining such specimens, Mr. North is indebted to Mr. W. J. Grimes, an enthusiastic oologist, who recently secured two nests of this species on the Tweed River. The nest is a beautiful structure, being bowl-shaped, and composed exteriorly of long twigs, entwined around the large broad leaves of *Ptarietia argyrodendron*, and other broad-leaved trees, some of the leaves measuring eleven inches in length by four inches in breadth. The leaves appear to have been picked when green, so beautifully do they fit the rounded form of the nest, one side of which is almost hidden by them. The interior of the nest is lined entirely with fine twigs. The eggs are two in number for a sitting, oval in form, being but slightly compressed at the smaller end, of a uniform creamy white very faintly tinged with green, the shell being comparatively smooth and slightly glossy. Although the cat-bird is usually included in the family of bower-building birds, Mr. North has never known or heard of its constructing a bower.

A CATALOGUE of the Australian birds in the Australian Museum, at Sydney, by Dr. E. P. Ramsay, is being published. Part III., which has just been issued, deals with Psittaci.

AS a substance peculiarly fitted, by reason of its high dispersive power, and transparency for ultra-violet rays, for study of the ultra-violet part of the spectrum, Herr Wolter has recently recommended, in a Hamburg serial, α-monobromnaphtalin.

With a prism of the liquid, he could trace the spectrum beyond N on a fluoresceïn-solution. Besides the above-named properties, the substance has for boiling-point 277° C.; it has no offensive smell like carbon sulphide, and its index of refraction varies much less with temperature than in the case of that liquid.

THE material resources of the southern part of Maryland are still so imperfectly known that a scientific expedition for the investigation of the district was recently organized. The expedition was formed under the joint auspices of the Johns Hopkins University, the Maryland Agricultural College, and the U.S. Geological Survey. An interesting report of the work done has been published in one of the Johns Hopkins University Circulars.

DR. ALFRED TUCKERMAN has compiled an excellent "Bibliography of the Chemical Influence of Light," which has been published as one of the Smithsonian miscellaneous collections. As the compiler had in view only the scientific aspects of the subject, he has omitted nearly all the practical applications, including that of photography. An index to the literature of photography is being prepared under the auspices of the committee for indexing chemical literature, of the American Association for the Advancement of Science.

THE College of Science, Imperial University, Japan, has issued the first part of the fourth volume of its Journal. It opens with a paper on the fœtal membranes of Chelonia, by K. Mitsukuri. After this come the following articles:—On the development of Araneina, by Kamakichi Kishinouye; observations on fresh-water Polyzoa, by A. Oka; on *Diplozoon nipponicum*, n. sp., by Seitaro Goto; a new species of Hymenomycetous Fungus injurious to the mulberry tree, by Nobujiro Tanaka; notes on the irritability of the stigma, by M. Miyoshi; notes on the development of the suprarenal bodies in the mouse, by Masamaro Inaba. Each of the papers is illustrated.

MR. C. C. VEVERS, Leeds, has sent us a copy of the fourth edition, illustrated, of his "Practical Amateur Photography." The volume is described in the preface as "a simple text-book for the beginner, and a handy work of reference for the advanced photographer." Mr. Vevers has also published an illustrated catalogue of photographic apparatus.

THE Manchester Microscopical Society has issued its Transactions and Annual Report, 1890. The volume includes two Presidential addresses by Prof. Milnes Marshall, papers and communications read by the members, and a list of members.

WE have received from Mr. William F. Clay, Edinburgh, a catalogue of scientific books which he offers for sale. The works relate to chemistry and allied sciences.

AS briefly announced in our report of the last meeting of the Paris Academy of Sciences a new compound of iron and carbon monoxide has been obtained by M. Berthelot, analogous to the nickel compound described last year by Messrs. Mond, Lang, and Quincke. In order to obtain it, the iron requires to be in a very finely divided state, and free from admixed oxide. It is most suitably obtained by reducing dried precipitated ferric oxide or oxide obtained by ignition of ferrous oxalate in a current of pure hydrogen. When carbon monoxide is led over metallic iron thus prepared, and the tube containing it gently warmed to about 45° C., the reaction commences, and if the issuing gas, after being washed through water, is ignited at a jet, the flame is observed to be quite different from that of pure carbon monoxide, being brilliantly luminous, almost white, and emitting rays which furnish a definite spectrum. Moreover, if a cold porcelain tile or evaporating basin is depressed upon the flame a deposit of metallic iron more or less admixed with oxide is obtained, indicating the existence in the issuing gas of the vapour of a ferruginous compound. A drop of dilute hydrochloric acid at once dissolves the stain, and the solution affords the ordinary reactions of iron, yielding Prussian blue with potassium ferrocyanide for instance. When the gases are passed through a strictured tube, such as is employed in Marsh's arsenic apparatus, a portion of which is heated to redness, an annular deposit of metallic iron is obtained, containing a slight amount of admixed carbon. M. Berthelot has not yet succeeded in obtaining sufficient of the new compound to condense it to the liquid form, but further experiments with that end in view are in progress. The formation of this volatile compound of iron and carbon monoxide will undoubtedly prove of great interest from a metallurgical point of view, as it may assist in elucidating several of the as yet little understood furnace reactions. M. Berthelot further expresses the opinion that it may help to explain the formation of bubble flaws in manufactured iron, which have so frequently led to such unfortunate results. In addition to the preparation of iron-carbonyl, M. Berthelot describes several new reactions of nickel carbonyl. It will be remembered that this substance is a liquid boiling at 46°, so volatile that, according to M. Berthelot, its vapour tension at 16° is a quarter of an atmosphere. A drop placed upon a glass plate rapidly volatilizes, the portion last to disappear being for a few moments cooled down by the evaporation of the first portion to such an extent as to form beautiful little crystals. When suddenly heated to 70° it detonates, the detonating reaction being expressed by the equation $Ni(CO)_4 = 2CO_2 + 2C + Ni$. When mixed with oxygen, simple agitation of the tube containing it over mercury brings about detonation. When oxygen is permitted to slowly gain access to the liquid oxide, a solid substance is formed, which is green if the oxygen is moist and brownish-yellow if dry. In contact with oil of vitriol the liquid compound appears to be unaffected for a few moments, but suddenly explodes with production of flame. Nitric oxide reacts in a most beautiful manner, either when passed into the liquid or its vapour, bright blue fumes being produced of a complex compound, which eventually subside, forming a blue solid. These blue vapours completely fill the whole vessel, and their formation affords one of the prettiest experiments yet described.

CONTEMPORANEOUSLY with the above work of M. Berthelot, Mr. Mond and his co-workers have also been conducting experiments with the view to the preparation of iron carbonyl, which have been so successful that a brief account of them was laid before the Chemical Society at their last meeting. Further particulars of these experiments will be given as soon as published.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus* ♀) from India, presented by Mr. Albert Job; an American Red Fox (*Canis fulvus*) from North America, presented by Mr. W. Reading; a Two-spotted Paradoxure (*Nandinia binotata*) from West Africa, presented by Mr. E. G. Parkinson; a Sinaitic Ibex (*Capra sinaitic*) from Palestine, presented by Sir James Anderson; two Gaimard's Rat-Kangaroos (*Hypsiprymnus gaimardi*) from Australia, presented by Mr. Walter Howker; a Cuckoo (*Cuculus canorus*), British, presented by Mr. Stacy Marks, R.A., F.Z.S.; two Red-billed Tree Ducks (*Dendrocygna autumnalis*) from America, presented by Mr. Keswick; two White-faced Tree Ducks (*Dendrocygna viduata*) from Brazil, presented by Captain C. A. Findlay, R.N.R.; a Common Viper (*Vipera berus*), British, presented by Mr. J. Sargeant; two White-headed Sea-Eagles (*Haliaëtus leucocephalus*) from North America, deposited; a Burchell's Zebra (*Equus burchelli* ♂), a Derbian Wallaby (*Halmaturus derbianus*), three Common Night Herons (*Nycticorax griseus*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE CAPTURE THEORY OF COMETS.—The last three numbers of the *Bulletin Astronomique* (April–June) have contained papers by M. L. Schulhof, "Sur les Grandes Perturbations des Comètes Périodiques," which place beyond doubt the idea that the periodic comets of our system are captured by the perturbing action of planets. The main object of the research was to develop the relations existing between the elements of the comet's orbit before and after its entrance within the sphere of activity of the disturbing planet. With the criteria obtained, and some results previously formulated by M. Tisserand, it is possible to decide the question as to the identity of two comets of which the time of revolution of one is known, even when the comet is believed to have passed several times within Jupiter's sphere of activity between two apparitions. This result is of the highest importance, for it is only by such means that individual comets can be identified. They cannot be recognized by their appearance, as they possess no peculiar characteristic that can be telescopically observed.

M. Schulhof suggests that, in the light of recent work, periodic comets should not now be classified according to their aphelion distances, but arranged in groups the mean aphelion distance of which approximates to the length of the semi-major axis of one or other of the planets. Such a division has been made for comets having periods between 10 and 10,000 years. From the tabulated results, it appears that four comets have aphelion distances which differ but little from the aphelion distance of Mercury. The Venus group numbers seven, the earth's group ten. Mars possesses four comets, and Jupiter twenty-three. Saturn has a family of nine, Uranus eight, and Neptune five.

WOLF'S PERIODIC COMET (*b* 1891).—The following ephemeris is from one given by Prof. Berberich in *Edinburgh Circular* No. 17. From *Astronomische Nachrichten*, No. 3042, it appears that Dr. Spitalier observed this comet on May 2; that is, before Prof. Barnard. The brightness on the date (May 4) of rediscovery by the latter observer has been taken as unity.

Ephemeris for Berlin Midnight.

The comet is now in Pisces, and in the beginning of September will pass through the Pleiades. M. Bigourdan, of Paris Observatory, observed it on June 12, and remarked that it was "une nébulosité ronde, d'environ 20″ de diamètre, de grandeur 13·3."

YORUBA AND GAZALAND.

AT the meeting of the Royal Geographical Society, on Monday, two papers were read: one by Mr. Alvan Millson, on the Yoruba country, West Africa, and the other by Mr. Denis Doyle, on a journey in Gazaland, in South-East Africa.

The ancient kingdom of Yoruba may be taken as one of the most interesting of the great tribal divisions of West Africa, between the Gold Coast and the Niger.

Landing at Lagos, the only natural harbour on a thousand miles of coast, a narrow entrance with a 15-feet bar leads into the intricate chain of waterways which extends, with few and slight interruptions, for 500 miles from the Volta river to the Benin branch of the Niger Delta. From the east and west, from the Benin river and the waters of the Dahomian frontier, the coast of the gulf is backed by intersecting channels of fresh water flowing steadily from either hand towards the Lagos outlet. In many places these narrow and brimming channels are separated from the onslaught of the Atlantic rollers by no more than five or six level yards of shifting sand; the spray from the ocean drifts over them, and the roar of the surf is heard by the native as he glides over their calm surface in his fragile canoe. These so-called "lagoons of the Bight of Benin" form but a small portion of the littoral river systems of West Africa; for from Cape Palmas to Cape Three Points the long Kroo coast is lined by inland waters for the greater part of 300 miles, and beyond the rocky spurs of the beautiful Gold Coast the Dahomian shores have the same remarkable formation. At right angles to this network of channels numerous rivers flow down from the uplands of the interior, carrying in their rapid streams vast quantities of sand and mud with which they busily build out the land. At first sight it seems strange that so many and such powerful streams, flowing strongly towards the sea should suddenly be turned aside from their courses by so narrow and fragile a barrier of shifting sand. To the influence of the sheltering headlands which jut out towards the south; to the rapid Guinea current which tears away the face of their rocky shores and hurries towards the east a ceaseless stream of sand; to the almost tideless ocean, and the absence of high winds, for the strength and duration of a West African tornado are but slight as compared with the hurricanes of the West Indies or the gales of our stormy coast; and above all to the enormous growths of floating papyrus and water-grass which line the inner banks of the lagoons, and prevent the swollen waters from breaking through into the ocean, are due the formation and continual development of this strange delta system. For these rivers are in most instances choked for many miles by a floating papyrus-sod bound together by wild water-figs and palm-wine palms (*Raphia vinifera*), and when the floods come down from the interior great masses of this floating vegetation are torn away and carried down to the lagoons and onwards towards the sea. Hundreds of acres of these grass islets are annually carried down from each of these rivers, and are driven against the banks of the littoral lagoons, where they lodge and grow, and eventually become anchored in their places by more permanent vegetation. In this manner the lagoon sides are padded for hundreds of yards, and even, in some instances, for two or three miles in depth on either hand, and their banks are protected from the wash of the current and the weight of the accumulated waters. By this means the frail barrier of sea-sand is strengthened, and the inland waters, although they frequently rise to a height of 5 to 6 feet above the sea-level, are effectually prevented from bursting through their banks. Not only are these growths a permanent protection to the land, but by their very nature, floating as they do on the surface of the water, they rise and fall with the floods, and are always ready with their assistance at the right time and place. Were all the rivers which feed the lagoons freed from their natural obstructions, as is the case with the Ogun river near Lagos, the interior to a distance of from thirty to seventy miles would be thrown open to commerce, and the wonderful system of inland navigation which fosters the coast traffic would be still further developed.

Mr. Millson went on to describe a journey from the coast to the interior, the country rising from terrace to terrace. He then spoke at some length of the Yoruba people and country.

About eighty miles from the coast, at Oda Ona Kekere, the dense forest suddenly gives place to open cultivated land, and a densely peopled country. Some three miles to the north of Odo Ona Kekere, from the crest of a rising in the undulating land the great city of Ibadan—the London of Negroland—comes full in view, extending for over six miles from east to west, and for more than three from north to south. Surrounded by its farming villages, 163 in number, Ibadan counts over 200,000 souls, while within the walls of the city itself at least 120,000 people are gathered. Its sea of brown roofs covers an area of nearly 16 square miles, and the ditches and walls of hardened clay which surround it are more than 18 miles in circumference. Its houses are built round courtyards with a single entrance, and form in themselves no mean defence against native inroads. Their walls of thick "adobe" are blank on the outer face, and the thatched roofs are made of a light covering of palm leaves and grass in order to avoid the danger of extensive conflagrations. In the winding rocky streets which intersect these large compounds in every direction, are countless market booths and occasional market places, where the inhabitants can purchase native produce, food, and European luxuries. In the same way, by the sides of the country roads, are built at irregular intervals varying from one to six miles, long low sheds close by some well or running water, where the farm women sit and "make their market." In the farms which extend throughout the country from horizon to horizon as one journeys through it, save where the land is too poor, or the fear of war has desolated the neighbourhood, can be heard the crowing of cocks, the barking of dogs, the shrill laughter of children, and the vociferous clamour of native homestead gossip. For among natives, as among seafaring folk at home, a hundred yards or so is no impediment to polite conversation. From this custom arises the disadvantage that the voices of the people being naturally pitched for distant communication cannot readily be restrained or focussed for nearer ranges of social intercourse. The consequent turmoil and shrill cries are apt at first to unsettle the nerves of an inexperienced traveller, but a few weeks' residence in the country not only accustoms one to their manner of speech, but inures one's system to the sudden shock of their sonorous voices.

Northward from Ibadan, which may be described as the centre of the chief military and commercial power in Yoruba, two days' journey—about 40 miles—through many villages, and a landscape dotted far and near with oil-palms (*Elæis guineensis*) along a road thronged with travellers, brings one to the capital of central Yoruba, Oyo (Awyaw). On leaving Ibadan, Mr. Millson passed, in the course of a morning's march, over 4700 men, women, and children, hurrying into the great city from the farm villages with loads of maize, beans, yams, yam flour, sweet potatoes, fowls, pigs, ducks; or driving cattle, sheep, and goats; or mounted on small native horses which amble quickly along under the combined influence of an Arab ring bit and an armed spur which leaves its traces in deep scores along the flanks of the poor animals. Far and wide the land has for generations, and indeed for centuries, been cultivated by these industrious natives. The hatchet, the fire and the hoe, have removed all traces of the original forest, save indeed where a dark trail of green across the landscape shows where the valley of some narrow watercourse or larger river is hidden among trees. For two or three years at most the land is allowed to lie fallow, while for three or four years double or treble crops are raised with no further cultivation than an occasional scrape with a hoe, and during its fallow time no further care is taken of it than to let a rank growth of reedy grass spring up some 6 or 8 feet in height. Among this grass can be seen the seedlings and young plants of a new forest, which would rapidly take possession were the land to be permanently deserted. In spite of this careless and exhausting method of cultivation the crops maintain an excellent average, and the same plot of ground serves for generations to support its owners.

Mr. Doyle, who accompanies King Gungunhana's two envoys to this country, described his journey from the Mashonaland plateau down through Gazaland to the mouth of the Limpopo. At first the journey was through a broken plateau country, rising to 5000 feet and over, and well adapted for farming operations. After fourteen days' travel, the country suddenly drops from a level of 4000–5000 feet to 860 feet above sea-level. For many miles the altitude was no more than 300 feet, and as it was the rainy season when Mr. Doyle and his companions passed through, they found the country almost entirely a swamp. The actual distance travelled was between 700 and 800 miles, which was traversed in forty-six days.

THE CONDITION OF SPACE.

The question of the condition of inter-planetary space, with special reference to the possibility that it offers a resistance to the passage of the heavenly bodies, has for long occupied the attention of astronomers, but is even yet far from receiving a satisfactory or definite solution. Three hypotheses seem to be more or less in vogue:—

(1) That it is filled with "ether," differing entirely in its properties from ordinary matter, and offering no resistance to the passage of solid or gaseous bodies. Radiant energy is transmitted by the vibratory motion of the ether, and possibly also the force of gravitation is transmitted by a rotatory motion, though, as Laplace points out, the velocity of the gravitation must be at least 7,000,000 times that of light.

(2) That it is filled with an ether more analogous to ordinary matter, which offers resistance, or with a highly rarefied gaseous medium similar in constitution to our atmosphere.

(3) That it is filled with ether, through which innumerable solid bodies of comparatively small size fly singly or in swarms. When they encounter one another, a gas, or a planet, they become luminous, and present the appearance of fireballs, meteorites; shooting-stars, meteors; comets, meteoric swarms; meteoric dust gives rise to the phenomenon of the aurora borealis. This theory has recently been much extended and admirably advocated by Prof. J. Norman Lockyer, in "The Meteoritic Hypothesis."

If the first hypothesis be true, and space offers no resistance to the passage of the planets, Laplace has shown (*Mém. Acad. des Sciences*, 1784) that any change in their orbits will be periodic, or, in other words, that, with only slight variations from time to time, the present condition of the solar system will continue indefinitely.

If the second hypothesis be true, the resistance, however slight it may be, will tend to retard the motion of the planets. In the case of the earth the friction between the outer layers of the atmosphere and the medium will retard the rotation of the earth, and increase the length of the day. There will also be a resistance to the motion of the earth in her orbit, which will tend to decrease the velocity, and therefore to lengthen the year; but, on the other hand, if the tangential velocity be decreased while the attraction of the sun remains the same, the earth will fall towards the sun, the mean distance will decrease, and therefore the time of revolution will be shortened.

If the third hypothesis be true, the rain of meteorites will have no effect on the rotation of the earth, but will tend to lessen the orbital velocity.

Laplace has discussed some consequences of the second hypothesis in "Mécanique Céleste," vii. 6, on secular variations in the movements of the moon and earth which might be produced by the resistance of an etherial medium spread round the sun. He assumes that the density of the medium is a function of the distance from the sun, and that the resistance varies as the square of the velocity. He concludes that the acceleration produced by the resistance of a fluid ether on the mean motion of the moon is, up to "the present time," insensible; and that the acceleration produced by the same ether on the motion of the earth would be less than 1/100 of that caused to the motion of the moon. These results are extended to other planets and to comets in x. 7, where it is shown that the distance at perihelion remains unchanged, and the only alteration in the orbit is a decrease in the length of the major axis and in the eccentricity.

The question is discussed from a mathematical point of view in several text-books (*e.g.* Tait and Steele, "Dynamics of a Particle," pp. 279, 379), but in all cases the mathematics are somewhat difficult, and various assumptions have to be made to render the solution possible.

In the case of the earth, if the resistance of the medium be small, the orbit may be considered to be circular, more especially as it follows from Laplace's results that the error introduced decreases with the time, since the orbit becomes more nearly circular. The following brief abstract of the popular treatment suggested by G. A. Hirn in his "Constitution de l'Espèce Céleste," pp. 104–108, with the substitution of English values, and the extension of the results to the meteoric hypothesis, may be not without interest at the present time.

Many of the data are so uncertain, that the rough approximations by which mathematical difficulties are avoided probably produce no great loss of arithmetical accuracy in the results.

The *vis viva* of the earth at the end of any period is equal to the *vis viva* at the commencement of the period, less the *vis viva* lost owing to the resistance of the medium, and increased by the *vis viva* due to the fall towards the sun. Transposing, and dividing by M/2—

$$v_r^2 = v_o^2 + v_s^2 - v_t^2.$$

Writing S for the attraction of the sun, and resolving along the radius vector A—

$$v_o^2/A_o = S, \quad \therefore v_o^2 = SA_o.$$

After a time t,

$$v_t^2/A = S\frac{A_o^2}{A_t}, \quad \therefore v_t^2 = SA_o^2/A_t.$$

The acceleration towards the sun is expressed by

$$\frac{d^2\mathrm{A}}{d_t^2} + \mathrm{S} \,.\, \frac{\mathrm{A}_o^2}{\mathrm{A}_t^2} = 0;$$

and integrating,

$$v_s^2 = 2\mathrm{SA}_o\left(\frac{\mathrm{A}_o}{\mathrm{A}_t} - 1\right).$$

Substituting and reducing,

$$v_r^2 = v_o^2\left(\frac{\mathrm{A}_o}{\mathrm{A}_t} - 1\right).$$

Hence the *vis viva* lost, owing to the resistance of the medium, is one-half of the *vis viva* gained by falling through $(\mathrm{A}_o - \mathrm{A}_t)$ towards the sun, and the presence of a very slightly resisting medium *increases* the velocity of the earth in its orbit. This increase is easily expressed, since, by Kepler's third law, we may replace $(\mathrm{A}_o/\mathrm{A}_t)^3$ by $(\mathrm{T}_o/\mathrm{T}_t)^2$, where $\mathrm{T}_o\mathrm{T}_t$ are the periodic times at the beginning and end of the period;

$$\therefore\ v_r^2 = v_o^2\left\{\left(\frac{\mathrm{T}_o}{\mathrm{T}_t}\right)^{\frac{2}{3}} - 1\right\}.$$

But the *vis viva* lost owing to the resistance is equal to the work done in forcing the sphere against the resistance of the medium through the distance passed over by the earth during the time. We may assume for simplicity that during the last 2000 years the length of the year has shortened by five seconds; and since the change in the radius vector would be very small, that $\mathrm{A} = 23300a$, where a is the radius of the earth, and hence that the distance through which the earth has passed is $2\pi\ 23300a\ 2000$.

M. Hirn, by theory and experiment, shows considerable reason for believing that the formula of Hutton, for the resistance of a medium in terms of the density δ, gives a result not far from the truth. Hence

$$\cdot 0451 \times (\pi a^2)^{1\cdot 1} \times \delta \times v_o^2 \times 2\pi\ 23300a\ 2000 = \frac{\mathrm{M}v_o^2}{2}\left\{\left(\frac{\mathrm{T}_o}{\mathrm{T}_t}\right)^{\frac{2}{3}} - 1\right\},$$

where

$$\left(\frac{\mathrm{T}_o}{\mathrm{T}_t}\right)^{\frac{2}{3}} - 1 = \left(1 + \frac{5}{31558150}\right)^{\frac{2}{3}} - 1 = \frac{1}{9467445}.$$

$$\therefore\ \frac{1}{\delta} = (\log^{-1} 14{\cdot}32278) \times ga^{\cdot 2}/\Delta,$$

where Δ is the absolute mass of unit volume of the material of the earth.

$$\therefore\ \frac{1}{\delta} = 5{\cdot}64 \times 10^{14} \text{ cubic feet.}$$

M. Hirn further points out that this decrease of five seconds in the length of the year during a period of 2000 years would be accompanied by a change in the longitude of the earth of more than 205″, an amount quite inadmissible since the time of Hipparchus, while the above results have shown that, to produce an acceleration so small as this, the medium must have a rarity such that one pound occupies 564 billions of cubic feet. And the volume occupied by a pound of the gas very nearly varies inversely as the number of seconds gained in the periodic time.

When we pass on to consider the retardation caused by the action of meteorites, we lose the guidance of M. Hirn, but are able to refer for data to Prof. Lockyer's treatise.

About 30 miles, or 158,400 feet per second, may be taken as the average velocity of meteorites (p. 68). Suppose the earth at rest, and struck by a meteorite weighing one pound with this velocity, the *vis viva* of the blow would be $\frac{1}{2g}(158400)^2 = 3{\cdot}98 \times 10^8$ absolute foot-pounds (p. 64).

But the earth is moving in its orbit with a velocity of 18·4 miles, or 97,130 feet per second; hence, of every three meteorites we may presume that two strike the front, and one the back hemisphere. Further, the velocity of the earth is, in the one case, to be added to, and, in the other case, subtracted from, the velocity of the meteorites. Again, we may assume that the earth is struck about equally all over each hemisphere, and that, owing to its attraction, the blows are vertical, and hence that the energy added and subtracted in each hemisphere in the direction of the motion of the earth is one-half of the total *vis viva*, or for three meteorites, each weighing a pound,

$$\frac{1}{2g}\left\{(158400 + 97130)^2 - \tfrac{1}{2}(158400 - 97130)^2\right\}$$

$$= 4{\cdot}58 \times 10^9 \text{ foot-pounds.}$$

Suppose that a meteorite weighing one pound has the specific heat 0·2, which is about double of that of iron; to raise it from −270° C. to 2000° C., 454 units of heat are required, which are equivalent to about $454 \times 44758 = 2 \times 10^7$ absolute foot-pounds of work—a quantity which may be neglected, in comparison with the total *vis viva* of the meteorite.

The weight of meteorites varies from tons to small specimens (p. 19), and hence we must assume an average weight of μ pounds. According to Newcomb, 20,000,000 meteorites a day enter our atmosphere (p. 69). We may again assume that the action has continued for 2000 years, and caused a shortening in the periodic time of five seconds.

The *vis viva* of the impacts,

$$\mu \times 4{\cdot}58 \times 10^9 \times \frac{20000000}{3} \times 365 \times 2000,$$

must be equal to the *vis viva* lost by the earth,

$$\tfrac{1}{2}\mathrm{M}v_o^2\left\{\left(\frac{\mathrm{T}_o}{\mathrm{T}_t}\right)^{\frac{2}{3}} - 1\right\}, \text{ which is } \frac{4\pi a^3 \times 10{\cdot}86 \times (97130)^2}{6 \times 9467445};$$

$$\therefore\ \mu = \frac{1{\cdot}95 \times 10^{33}}{1{\cdot}115 \times 10^{19} \times 2000 \times 9467445}$$

$$= 9240 \text{ pounds, or over 4 tons.}$$

In this case, also, the average mass of the meteorites varies inversely as the shortening of the periodic time. Thus, if the average weight of meteorites is 9 pounds, the shortening would be only 0·005 second—an amount probably inappreciable.

SYDNEY LUPTON.

THE FLOWERS OF THE PYRENEES AND THEIR FERTILIZATION BY INSECTS.[1]

THE observations described in this work were made in the Vallée de Luz (Hautes Pyrénées, France), in August 1889 and June 1890, between 900 and 2200 metres altitude. The author has noticed 1801 visits, brought by 507 different insects to 261 different flowers. In the list of the visits, date and altitude are always noted, and in many cases particulars are given about the special habits of insects in visiting flowers. Many of the mentioned insects were not before seen visiting flowers.

The contrivances by which the flowers are fertilized are described for the following species: *Merendera Bulbocodium*, *Asphodelus albus* (lepidopterophilous, proterogynous), *Hyacinthus amethystinus* (proterandrous, adapted to long-tongued bees), *Iris pyrenaica*, *Antirrhinum sempervirens*, *Linaria origanifolia* (adapted to bees, with special entrance for Lepidoptera or Bombylidæ), *Linaria pyrenaica*, *Horminum pyrenaicum* (gynomonœcious), *Scutellaria alpina* (adapted to long-tongued bees, with special entrance for Lepidoptera), *Teucrium pyrenaicum* (adapted to bees, with entrance for Lepidoptera), *Dianthus monspessulanus* (lepidopterophilous), *Alsine* sp., *Alsine verna*, *Aconitum pyrenaicum* (resembles the *A. lycoctonum*), *A. Anthora*, *Aquilegia pyrenaica*, *Brassica montana* (lepidopterophilous), *Roripa pyrenaica*, *Reseda glauca*, *Geranium cinereum* (proterandrous, gynodiœcious), *Saxifraga longifolia* (proterandrous), *Potentilla alchemilloides*, *Potentilla fragariastrum*.

Some details are given about the construction of the flowers in the following species: *Cirsium eriophorum*, *C. monspessulanum*, *Carduus medius*, *C. carlinoides*, *Centaurea Scabiosa*, *Gnaphalium Leontopodium*, *Angelica pyrenæa*. Almost all those species are illustrated (94 figures), and the explanation of each figure is given in French and in Dutch.

General conclusions:—The relative number of hemitrope Diptera (Syrphidæ, Conopidæ, and Bombylidæ), of allotrope Hymenoptera (all Hymenoptera except the bees), of long-tongued not-social bees and of Coleoptera decreases with increasing altitude. The hemitrope Diptera (all Diptera except those mentioned above) become on the contrary relatively more numerous with increasing altitude; this seems to be also the case with the social long-tongued bees (represented in the Pyrenees by *Bombus* and *Psithyrus*). Müller came to the same conclusions about the influence of altitude upon the same groups of insects in the Alps.

---

[1] "De Pyreneeënbloemen en hare bevruchting door insecten," 226 pages, with five plates, a French *résumé*, and the explanation of the plates in French. In *Botanisch Jaarboek*, iii., 1891, published by the Botanical Society Dodonæa, in Ghent, Belgium).

On the other hand, Müller noticed that in the Alps the relative number of Lepidoptera increases, of hemitrope Hymenoptera (short-tongued bees) decreases in the higher parts of the mountains. The influence of altitude upon those two groups of insects is not evident in the Pyrenees.

The Lepidoptera—which in the Alps, according to Müller, are very numerous—are much less numerous in the Pyrenees. All the allotrope insects (Coleoptera, allotrope Diptera, and allotrope Hymenoptera) are relatively more numerous in the Pyrenees than in the Alps. The hemitrope Hymenoptera (short-tongued bees) are somewhat more numerous in the Pyrenees than in the Alps; the hemitrope Diptera (Syrphidæ, Conopidæ, and Bombylidæ) are almost equally represented in both the mountains. The eutrope Hymenoptera (long-tongued bees) seem to be equally numerous in the Pyrenees and in the Alps; in both countries, the humble-bees are predominant, and the not-social long-tongued bees are scarce.

The following table will enable students to compare the flora of the Pyrenees with that of the Alps :—

	Pyrenees.			Alps.	
	Species.	Per cent.		Species.	Per cent.
Pollen flowers (class Po) ...	12	(4·6)	...	14	(3·3)
Fl. with free-exposed honey (class A)	34	(13·0)	...	42	(10·1)
Fl. with partially concealed honey (AB)	45	(17·2)	...	61	(14·6)
Fl. with quite concealed honey (B).....................	37	(14·1)	...	66	(15·3)
Associated flowers with quite concealed honey (B′)	48	(18·4)	...	84	(20·2)
Flowers adapted to bees (Bb)	73	(27·9)	...	110	(26·4)
Flowers adapted to Lepidoptera (Vb)	12	(4·6)	...	39	(9·3)

The allotrope flowers (Po, A, AB) are relatively more numerous, the lepidopterophilous flowers (Vb) are less numerous in the Pyrenees than in the Alps; we have seen that the same differences exist for the corresponding groups of insects.

The hemitrope flowers (B, B′) are a little more numerous in the Alps than in the Pyrenees; the contrary occurs with the hemitrope insects. There is here accordingly no concordance in the geographical distribution between flowers and insects; but the hemitrope insects are not so constant in the choice of their flowers as the allotrope insects and the Lepidoptera; their influence upon the distribution of the corresponding flowers is therefore not so great as that of the two latter groups. The class Bb and the long-tongued bees are nearly equally represented in both the mountains. The parallelism which occurs between the relative abundance of the classes Po, A, AB, Bb, and Vb, and the relative abundance of corresponding insects, agrees very nicely with the theory of flowers.

It may be observed that in the Pyrenees, with reference to the biological floral organization, the Choripetalæ are, on the whole, on a lower level than the Sympetalæ. Only a small number of Monocotyledoneæ could be observed.

University, Ghent. J. MacLeod.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Cambridge.—The Council of the Senate have appointed Mr. E. Hill, of St. John's College, to be a governor of Woodbridge School, under the new scheme.

The Harkness Scholarship in Geology and Palæontology has been awarded to Herbert Kynaston, of King's College.

Mr. A. A. Kanthack has been elected to the John Lucas Walker Studentship in Pathology, vacated by the election of Mr. J. G. Adami to a Fellowship at Jesus College. Mr. Kanthack is at present in India as a member of the Leprosy Commission.

The managers of the John Lucas Walker Fund have made a grant of £60 to Mr. E. H. Hankin, Fellow of St. John's, for the purchase of bacteriological apparatus required for his researches.

I. H. Burkill, of Caius College, has been appointed Assistant Curator of the Herbarium.

Prof. Ewing advertises for a demonstrator in mechanism, who has had a workshop training in mechanical engineering. The salary is £150 a year.

The annual report of the Local Lectures Syndicate, published in the *University Reporter* of June 23, records a large amount of useful work in so-called University extension. The number of courses given in 1890-91 was 135, with an average attendance of 10,947. The average attendance at the classes held after lecture was 4916, the number of weekly papers sent in 2266, and the number of candidates examined for certificates 1547. The following passages refer to a fresh departure of considerable interest, and of far-reaching possibilities in the future :—

"The grant for technical education which has been put at the disposal of the County Councils has led to an extension of the work of the Syndicate, and it seems not improbable that if a grant of this nature is made permanent a considerable demand will be made upon their staff of lecturers. In Devonshire they have provided at the request of the County Council a Lecturer on Chemistry and a Lecturer on Mechanics, in each case with special reference to applications to agriculture. The lectures in chemistry were given at six centres, those in mechanics at five. The average weekly attendance was—at lectures about 40, at classes about 25, at each centre. In all, 64 students presented themselves for examination, of whom 44 passed, 14 obtaining distinction. The audience comprised a number of boys from elementary and secondary schools, and some working men and farmers and schoolmasters, in addition to the usual mixed audience. The lectures were of necessity arranged rather hurriedly, without sufficient time for the local authorities to complete their organization, and they can only be regarded as an experiment. The Syndicate have reason to think that the experiment has been as successful as under the circumstances could be expected. . . .

"Having regard to the probability of a considerable demand for lecturers in connection with the County Councils, the Syndicate have added to their list several new lecturers whose attainments mark them out as suitable for this work. And in order that the lecturers may have practical acquaintance with the applications of their science to the uses of agriculture, the Syndicate have arranged that they should pay visits to farms of various characters and to the experimental farm at Woburn. These visits are paid under the experienced superintendence of Mr. H. Robinson, of Downing College, the assistant to the Professor of Chemistry. Mr. Robinson conducts also a course of laboratory work with the lecturers, with special reference to agricultural investigations. The Syndicate desire to express their grateful sense of the help which Prof. Liveing and Mr. Robinson have so liberally given. The provision of teaching and guidance in Cambridge for the scientific study of subjects connected with agriculture appears to the Syndicate to be so important for the training of students who may become lecturers on their staff, that they will endeavour to secure a continuance of this assistance, and are prepared to devote a portion of their funds to the purpose."

The *Ordo Senioritatis* for the year shows that 6 D.Sc. degrees have been conferred, 19 M.D. degrees, 72 M.B., and 70 B.C. These figures bespeak the steady growth of the faculties of science and medicine, the numbers in medicine being larger than in any previous year.

SOCIETIES AND ACADEMIES.

London.

Royal Society, June 11.—"On Electrical Evaporation." By William Crookes, F.R.S.

It is well known that when a vacuum tube is furnished with internal platinum electrodes, the adjacent glass, especially near the negative pole, speedily becomes blackened, owing to the deposition of metallic platinum. The passage of the induction current greatly stimulates the motion of the residual gaseous molecules; those condensed upon and in the immediate neighbourhood of the negative pole are shot away at an immense speed in almost straight lines, the speed varying with the degree of exhaustion and with the intensity of the induced current. Platinum being used for the negative pole, not only are the gaseous molecules shot away from the electrode, but the passage of the current so affects the normal molecular motions of the metal as to remove some of the molecules from the sphere of attraction of the mass, causing them to fly off with the stream of gaseous molecules proceeding from the negative pole, and to adhere to any object near it. This property was, I believe, first pointed out by Dr. Wright, of Yale College, and some interesting experiments are described by him in the *American Journal of Science and Arts.*[1] The process has been much used for the production of small mirrors for physical apparatus.

This electrical volatilization or evaporation is very similar to ordinary evaporation by the agency of heat. Cohesion in solids varies according to physical and chemical constitution; thus every kind of solid matter requires to be raised to a certain temperature before the molecules lose their fixity of position and are rendered liquid, a result which is reached at widely different temperatures. If we consider a liquid at atmospheric pressure—say, for instance, a basin of water in an open room—at molecular distances the boundary surface between the liquid and the superincumbent gas will not be a plane, but turbulent like a a stormy ocean. The molecules at the surface of the liquid dart to and fro, rebound from their neighbours, and fly off in every direction. Their initial velocity may be either accelerated or retarded, according to the direction of impact. The result of a collision may drive a molecule in such a direction that it remains part and parcel of the liquid; on the other hand, it may be sent upwards without any diminution of speed, and it will then be carried beyond the range of attraction of neighbouring molecules and fly off into and mingle with the superincumbent gas. If a molecule of the liquid has been driven at an angle with a velocity not sufficient to carry it beyond the range of molecular attraction of the liquid, it may still escape, since, in its excursion upwards, a gaseous molecule may strike it in the right direction, and its temporary visit may be converted into permanent residence.

The intrinsic velocity of the molecules is intensified by heat and diminished by cold. If, therefore, we raise the temperature of the water without materially increasing that of the surrounding air, the excursions of the molecules of the liquid are rendered longer and the force of impact greater, and thus the escape of molecules into the upper region of gas is increased, and we say that evaporation is augmented.

If the initial velocities of the liquid molecules can be increased by any other means than by raising the temperature, so that their escape into the gas is rendered more rapid, the result may be called "evaporation" just as well as if heat had been applied.

Hitherto I have spoken of a liquid evaporating into a gas; but the same reasoning applies equally to a solid body. But whilst a solid body like platinum requires an intense heat to enable its upper stratum of molecules to pass beyond the sphere of attraction of the neighbouring molecules, experiment shows that a very moderate amount of negative electrification superadds sufficient energy to enable the upper stratum of metallic molecules to fly beyond the attractive power of the rest of the metal.

If a gaseous medium exists above the liquid or solid, it prevents to some degree the molecules from flying off. Thus both ordinary and electrical evaporation are more rapid in a vacuum than at the ordinary atmospheric pressure.

I have recently made some experiments upon the evaporation of different substances under the electric stress.

Evaporation of Cadmium.—A U-shaped tube was made, having a bulb in each limb. The platinum poles were at the extremities of each limb, and in each bulb was suspended from a small platinum hook a small lump of cadmium, the metal having been cast on to the wire. The wires were each weighed with and without the cadmium. The tube was exhausted, and the lower half of the tube was inclosed in a metal pot containing paraffin wax, the temperature being kept at 230° C. during the continuance of the experiment. A deposit around the negative pole took place almost immediately, and in five minutes the bulb surrounding it was opaque with deposited metal. The positive pole with its surrounding luminosity could be easily seen the whole time. In thirty minutes the experiment was stopped, and after all was cold the tube was opened and the wires weighed again. The results were as follows:—

	Positive pole.	Negative pole.
Original weight of cadmium	9·34 grs.	9·38 grs.
Weight after experiment	9·25 ,,	1·86 ,,
Cadmium volatilized in 30 mins. ...	0·09 ,,	7·52 ,,

Finding that cadmium volatilized so readily under the action of the induction current, a large quantity, about 350 grs., of the pure metal was sealed up in a tube, and the end of the tube containing the metal was heated to a little above the melting-point; the molten metal being made the negative pole, in a few hours the whole quantity had volatilized and condensed in a thick layer on the far end of the tube, near, but not touching, the positive pole.

Volatilization of Silver.—Silver was the next metal experimented upon. The apparatus was similar to that used for the cadmium experiments. Small lumps of pure silver were cast on the ends of platinum wires, and suspended to the inner ends of platinum terminals passing through the glass bulb. The platinum wires were protected by glass, so that only the silver balls were exposed. The whole apparatus was inclosed in a metal box lined with mica, and the temperature was kept as high as the glass would allow without softening. The apparatus was exhausted to a dark space of 3 mm., and the current was kept on for 1½ hours. The weights of silver, before and after the experiment, were as follows:—

	Positive pole.	Negative pole.
Original weight of silver ...	18·14 grs.	24·63 grs.
Weight after the experiment ...	18·13 ,,	24·44 ,,
Silver volatilized in 1½ hours ...	0·01 ,,	0·19 ,,

In this tube it was not easy to observe the spectrum of the negative pole, owing to the rapid manner in which the deposit obscured the glass. A special tube was therefore devised, of the following character:—A silver rod was attached to the platinum pole at one end of the tube, and the aluminium positive pole was at the side. The end of the tube opposite the silver pole was rounded, and the spectroscope was arranged to observe the light of the volatilizing silver "end on." In this way the deposit of silver offered no obstruction to the light, as none was deposited except on the sides of the tube surrounding the silver. At a vacuum giving a dark space of about 3 mm. from the silver, a greenish-white glow was seen to surround the metal. This glow gave a very brilliant spectrum. The spark from silver poles in air was brought into the same field of view as the vacuum glow, by means of a right-angled prism attached to the spectroscope, and the two spectra were compared. The two strong green lines of silver were visible in each spectrum; the measurements taken of their wave-lengths were 3344 and 3675, numbers which are so close to Thalén's numbers as to leave no doubt that they are the silver lines. At a pressure giving a dark space of 2 mm. the spectrum was very bright, and consisted chiefly of the two green lines and the red and green hydrogen lines. The intercalation of a Leyden jar into the circuit does not materially increase the brilliancy of the lines, but it brings out the well-known air lines. At this pressure not much silver flies off from the pole. At a higher vacuum the luminosity round the silver pole gets less and the green lines vanish. At an exhaustion of about one-millionth of an atmosphere the luminosity is feeble, the silver pole has exactly the appearance of being red-hot, and the volatilization of the metal proceeds rapidly.[1]

If, for the negative electrode, instead of a pure metal such as cadmium or silver, an alloy was used, the different components might be shot off to different distances, and in this way make an electrical separation—a sort of fractional distillation. A negative terminal was formed of clean brass, and submitted to the electrical discharge *in vacuo*; the deposit obtained was of the colour of brass throughout, and on treating the deposit chemically I could detect no separation of its component metals, copper and zinc.

A remarkable alloy of gold and aluminium, of a rich purple colour, has been kindly sent me by Prof. Roberts-Austen. Gold being very volatile in the vacuum tube, and aluminium almost fixed, this alloy was likely to give different results from those yielded by brass, where both constituents fly off with almost equal readiness. The Au-Al alloy had been cast in a clay tube, in the form of a rod 2 cm. long and about 2 mm. in diameter.

---

[1] Third Series, vol. xii. p. 49, January 1877; and vol. xiv. p. 169, September 1877.

[1] Like the action producing volatilization, the "red heat" is confined to the superficial layers of molecules only. The metal instantly assumes, or loses, the appearance of red heat the moment the current is turned on or off, showing that, if the appearance is really due to a rise of temperature, it does not penetrate much below the surface. The extra activity of the metallic molecules necessary to volatilize them is, in these experiments, confined to the surface only, or the whole mass would evaporate at once, as when a metallic wire is deflagrated by the discharge of a powerful Leyden jar. When this extra activity is produced by artificial heat one of the effects is the emission of red light; so it is not unreasonable to imagine that when the extra activity is produced by electricity the emission of red light should also accompany the separation of molecules from the mass. In comparison with electricity, heat is a wasteful agent for promoting volatilization, as the whole mass must be raised to the requisite temperature to produce a surface action merely; whereas the action of electrification does not appear to penetrate much below the surface.

It was sealed in a vacuum tube as the negative pole, an aluminium pole being at the other side. Part of the alloy, where it joined the platinum wire passing through the glass, was closely surrounded with a narrow glass tube. A clean glass plate was supported about 3 mm. from the rod of alloy. After good exhaustion the induction current was passed, the alloy being kept negative. Volatilization was very slight, but at the end of half an hour a faint purple deposit was seen both on the glass plate and on the walls of the tube. On removing the rod from the apparatus it was seen that the portion which had been covered by the small glass tube retained its original purple appearance, while the part that had been exposed to electrical action had changed to the dull white colour of aluminium. Examined under the microscope, the whitened surface of the Austen alloy was seen to be pitted irregularly, with no trace of crystalline appearance.

This experiment shows that, from an alloy of gold and aluminium, the gold is the first to volatilize under electrical influence, the aluminium being left behind. The purple colour of the deposit on glass is probably due to finely-divided metallic gold. The first deposit from a negative pole of pure gold is pink; this changes to purple as the thickness increases. The purple then turns to green, which gets darker and darker until the metallic lustre of polished gold appears.

If we take several liquids of different boiling-points, put them under the same pressure, and apply the same amount of heat to each, the quantity passing from the liquid to the gaseous state will differ widely in each case.

It was interesting to try a parallel experiment with metals, to find their comparative volatility under the same conditions of temperature, pressure, and electrical influence. It was necessary to fix upon one metal as a standard of comparison, and for this purpose I selected gold, its electrical volatility being great, and it being easy to prepare in a pure state.

An apparatus was made that was practically a vacuum tube with four negative poles at one end and one positive pole at the other. By a revolving commutator I was able to make electrical connection with each of the four negative poles in succession for exactly the same length of time (about six seconds); by this means the variations in the strength of the current, the experiment lasting some hours, affected each metal alike.

The exposed surface of the various metals used as negative poles was kept uniform by taking them in the form of wires that had all been drawn through the same standard hole in the drawplate, and cutting them by gauge to a uniform length; the actual size used was 0·8 mm. in diameter and 20 mm. long.

The comparison metal, gold, had to be used in each experiment; the apparatus thus enabled me to compare three different metals each time. The length of time that the current was kept on the revolving commutator in each experiment was eight hours, making two hours of electrification for each of the four negative electrodes; the pressure was such as to give a dark space of 6 mm.

The fusible metals, tin, cadmium, and lead, when put into the apparatus in the form of wires, very quickly melted. To avoid this difficulty a special form of pole was devised. Some small circular porcelain basins were made, 9 mm. diameter; through a small hole in the bottom a short length of iron wire, 0·8 mm. in diameter, was passed, projecting downwards about 5 mm.; the basin was then filled to the brim with the metal to be tested, and was fitted into the apparatus exactly in the same way as the wires; the internal diameter of the basins at the brim was 7 mm., and the negative metal filed flat was thus formed of a circular disk 7 mm. diameter. The standard gold pole being treated in the same way, the numbers obtained for the fusible metals can be compared with gold, and take their place in the table.

The following table of the comparative volatilities was in this way obtained, taking gold as = 100:—

Palladium	108·00	Platinum	44·00
Gold	100·00	Copper	40·24
Silver	82·68	Cadmium	31·99
Lead	75·04	Nickel	10·99
Tin	56·96	Iridium	10·49
Brass	51·58	Iron	5·50

In this experiment equal surfaces of each metal were exposed to the current. By dividing the numbers so obtained by the specific gravity of the metal, the following order is found:—

Palladium	9·00	Copper	2·52
Silver	7·88	Platinum	2·02
Tin	7·76	Nickel	1·29
Lead	6·61	Iron	0·71
Gold	5·18	Iridium	0·47
Cadmium	3·72		

Aluminium and magnesium appear to be practically non-volatile under these circumstances.

The order of metals in the table shows at once that the electrical volatility in the solid state does not correspond with the order of melting-points, of atomic weights, or of any other well-known constant. The experiment with some of the typical metals was repeated, and the numbers obtained did not vary materially from those given above, showing that the order is not likely to be far wrong.

It is seen in the above table that the electrical volatility of silver is high, while that of cadmium is low. In the two earlier experiments, where cadmium and silver were taken, the cadmium negative electrode in 30 minutes lost 7·52 grs., whilst the silver negative electrode in 1½ hours only lost 0·19 gr. This apparent discrepancy is easily explained by the fact (already noted in the case of cadmium) that the maximum evaporation effect, due to electrical disturbance, takes place when the metal is at or near the point of liquefaction. If it were possible to form a negative pole *in vacuo* of molten silver, then the quantity volatilized in a given time would be probably more than that of cadmium.

Gold having proved to be readily volatile under the electric current, an experiment was tried with a view to producing a larger quantity of the volatilized metal. A tube was made having at one end a negative pole composed of a weighed brush of fine wires of pure gold, and an aluminium pole at the other end.

The tube was exhausted and the current from the induction coil put on, making the gold brush negative; the resistance of the tube was found to increase considerably as the walls became coated with metal, so much so that, to enable the current to pass through, air had to be let in after a while, depressing the gauge ½ mm.

The weight of the brush before experiment was 35·4940 grs. The induction current was kept on the tube for 14½ hours; at the end of this time the tube was opened and the brush removed. It now weighed 32·5613, showing a loss of 2·9327 grs. When heated below redness the deposited film of gold was easily removed from the walls of the tube in the form of very brilliant foil.

After having been subjected to electrical volatilization, the appearance of the residual piece of gold under the microscope, using a ¼-inch object-glass, was very like that of electrolytically deposited metal, pitted all over with minute hollows.

This experiment on the volatilization of gold having produced good coherent films of that metal, a similar experiment was tried, using a brush of platinum as a negative electrode. On referring to the table it will be seen that the electrical volatility of platinum is much lower than that of gold, but it was thought that by taking longer time a sufficient quantity might be volatilized to enable it to be removed from the tube.

The vacuum tube was exhausted to such a point as to give a dark space of 6 mm., and it was found, as in the case of gold, that as a coating of metal was deposited upon the glass the resistance rapidly increased, but in a much more marked degree, the residual gas in the tube apparently becoming absorbed as the deposition proceeded. It was necessary to let a little air into the tube about every 30 minutes, to reduce the vacuum. This appears to show that the platinum was being deposited in a porous spongy form, with great power of occluding the residual gas.

Heating the tube when it had become this way non-conducting liberated sufficient gas to depress the gauge of the pump 1 mm., and to reduce the vacuum so as to give a dark space of about 3 mm. This gas was not re-absorbed on cooling, but on passing the current for ten minutes the tube again refused to conduct, owing to absorption. The tube was again heated, with another liberation of gas, but much less than before, and this time the whole was re-absorbed on cooling.

The current was kept on this tube for 25 hours; it was then opened, but I could not remove the deposited metal except in small pieces, as it was brittle and porous. Weighing the brush that had formed, the negative pole gave the following results:—

	Grains.
Weight of platinum before experiment	10·1940
,, ,, after experiment	8·1570
Loss by volatilization in 25 hours	2·0370

Another experiment was made similar to that with gold and platinum, but using silver as the negative pole, the pure metal being formed into a brush of fine wires. Less gas was occluded during the progress of this experiment than in the case of platinum. The silver behaved the same as gold, the metal deposited freely, and the vacuum was easily kept at a dark space of 6 mm. by the very occasional admission of a trace of air. In 20 hours nearly 3 grs. of silver were volatilized. The deposit of silver was detached without difficulty from the glass in the form of bright foil.

Chemical Society, June 4.—Mr. W. Crookes, F.R.S., Vice-President, in the chair.—The following papers were read:—The molecular refraction and dispersion of various substances in solution, by Dr. J. H. Gladstone, F.R.S. The paper is a continuation of that laid before the Society in March last, and deals with solid and gaseous substances that have been dissolved in water and other liquids for examination. The results are given in several tables. In the case of organic compounds, the theoretical and experimental numbers are frequently in close agreement. Hydrogen chloride, bromide, and iodide give figures for the molecular refraction and dispersion much higher than the sum of the hydrogen and halogen as determined from the paraffin compounds, and the values rise as the dilution becomes greater. Selenious and selenic acids afford optical values much less than what would be expected from the known values of their constituents. Metaphosphoric acid does the same. The data relating to solutions of salts and alkalies will afford material for a revision of the refraction equivalents of the different metals, and of the electro-negative elements with which they are combined. Ammonia, in contrast with the hydrides of chlorine, bromine, and iodine, appears to be uniform in its optical properties, whatever the strength of the solution. The refraction equivalents of cerium, didymium, and lanthanum were found about 12·4, 16·4, and 15·5 respectively. The molecular refraction for ClO_3 in its salts dissolved in water comes out at about 18·3, that for BrO_3 at 24·9, and for IO_3 at 33·8.—The nature of solutions as elucidated by a study of the densities, heat of dissolution, and freezing-points of solutions of calcium chloride, by S. U. Pickering. The curves representing these properties were examined in the same way as those for sulphuric acid, and similar conclusions are drawn—namely, that changes of curvature, which occur at certain points which are the same whatever property is examined represent the existence of hydrates in solution. The simplest hydrates indicated consist of $CaCl_2$ with 6, 7, and $8H_2O$; more complex hydrates also exist, as in the case of sulphuric acid.—Note on a recent criticism by Mr. Sydney Lupton of the conclusions drawn from a study of various properties of sulphuric acid solutions, by S. U. Pickering. Mr. Lupton (*Phil. Mag.*, xxxi. 418) applies a single parabolic equation to a portion of one of the author's sulphuric acid density curves, where a change of curvature was supposed to exist, and shows that it represents the results accurately if the experimental error is of a certain magnitude. This magnitude is between 1000 and 10,000 per cent. greater than the ascertained magnitude, and the equation represents all errors of like signs as grouped together. Such a representation cannot disprove the existence of the particular change of curvature under examination, still less that of the 101 others examined by the author. The hydrate on which Mr. Lupton considers that his investigation throws "very grave suspicion" happens to be the one which the author has isolated in the crystalline condition. In the discussion which followed, Prof. Ramsay doubted the validity of Mr. Pickering's methods of differentiating his curves. His own experience was that it was impossible to obtain results nearer than 2 or 3 per cent. to the truth. Dr. Armstrong said that he was prepared to believe in the existence of hydrates in solution, but could not imagine that the 102 breaks in the sulphuric acid curves, for example, could be interpreted as evidence of as many distinct hydrates. He was inclined to think that the breaks might be due to change both in the complex water molecules and the sulphuric acid. He was inclined to believe that the hydrate, to which Mr. Lupton's conclusions related, did not begin to form in solution until the temperature sank to within a few degrees of its point of fusion. Dr. Morley said that a break in the curve should indicate that some new hydrate had just begun to form, but need not show what that hydrate was. Thus, a liquid of the composition $CaCl_28H_2O$ might be expected to contain, besides the hydrate $CaCl_28H_2O$, also higher and lower hydrates, such as $CaCl_29H_2O$ and $CaCl_27H_2O$. Prof. Rücker said that, in reality, Mr. Pickering's results were obtained, not by calculation, but by a method of observation and experiment applied to curves, which themselves represented the results of other experiments. It was admitted that the curves had to be specially drawn, and the scale of the co-ordinates carefully chosen, if the results were to be satisfactory, and probably the conclusions arrived at depended in a large measure on the details of this preliminary adjustment. In the case of the more striking changes in direction and curvature which were clearly visible in the original curve, the various differential curves did not add much to the information it supplied. He thought that the evidence afforded by these secondary curves of changes of curvature, not otherwise detected, was of the most untrustworthy character. Mr. Pickering said that Mr. Lupton's equation represented the rate of change of the densities as a straight line, while the figure which the actually observed rate of change formed was as different from a straight line as possible. The figures here referred to were the first differential figures (rate of change) deduced directly from the determinations themselves; the question of the accuracy attainable in differentiating a graph, raised by Prof. Ramsay, did not apply. He thought that Prof. Armstrong was somewhat rash in holding that a particular hydrate did not exist in solution at moderately high temperatures, because he had recognized it at low temperatures only, especially as he (the speaker) had been led to search for it, and finally to isolate it from results obtained at high temperatures. The multiplicity and complexity of the hydrates indicated must endanger the acceptance of his conclusions amongst chemists; and he was perfectly ready to accept any other explanation of the changes with weak solutions.—Ethylic $\alpha\alpha'$-dimethyl-$\alpha\alpha'$-diacetylpimelate and its decomposition-products, by Dr. F. S. Kipping, and J. E. Mackenzie. This paper contains an account of the preparation and properties of the following compounds: ethylic $\alpha\alpha'$-dimethyl-$\alpha\alpha'$-diacetylpimelate, $\alpha\alpha'$-dimethyl-$\alpha\alpha'$-diacetylpentane, $\alpha\alpha'$-dimethyl-α-acetylcaproic acid, $\alpha\alpha'$-dimethylpimelic acid, and ethylic-$\alpha\alpha'$-dimethylpimelate.—Volatile platinum compounds, by W. Pullinger. The author has studied the volatile compounds of platinum with chlorine and carbon monoxide described by Schützenberger. He describes their behaviour when heated in various gases; as they do not completely volatilize, a determination of the vapour-density was not possible. He describes a non-volatile compound of the formula $PtCl_6.C_2O_2$, and has also prepared the compound $PtBr_2CO$. Directions are given for the preparation of platinic bromide and iodide, from which it appears that spongy platinum readily dissolves in hot solutions of bromine in hydrobromic acid or of iodine in hydriodic acid.

Mineralogical Society, June 16.—R. H. Scott, F.R.S., President, in the chair.—The following papers were read:—On the occurrence of sapphire in Scotland, by Prof. M. Forster-Heddle.—On the optical properties of gyrolite, by Prof. M. Forster-Heddle.—On Fresnel's wave-surface, by L. Fletcher, F.R.S.

Linnean Society, June 18.—Prof. Stewart, President, in the chair.—Mr. W. H. Beeby exhibited specimens of *Hieracium protractum* and other plants collected in Shetland.—Mr. Stuart Samuel exhibited a dwarf specimen of *Acer palmatum*, and made some remarks on the dwarf trees artificially produced by the Japanese.—Mr. R. V. Sherring showed some cases of dried Bananas, and described a new method of preservation adopted in Jamaica to save waste of small parcels of fruit which would be otherwise unsaleable.—Mr. A. W. Bennett exhibited and made remarks upon a specimen of *Selaginella lepidophylla*, which was found to possess remarkable vitality, and upon proper treatment to resume its normal appearance after having been gathered some months.—Dr. R. A. Prior exhibited samples of the Spiked Star of Bethlehem (*Ornithogalum pyrenaicum*), and stated that, although described in British floras as a rare plant, it is so abundant on the hill pastures around Bath that it is brought to the market there in large quantities under the name of French asparagus, and sold for a penny a bunch.—Mr. R. A. Rolfe showed two hybrid *Odontoglossums* with the parent plants—namely, *O. Wilckeanum* (produced from *O. crispum* and *O. luteopurpureum*) and *O. excellens* (produced from *O. pescatorei* and *O. triumphans*). These had first appeared as natural hybrids out of imported plants, and the parentage was subsequently ascertained under cultivation.—On behalf of Sir George Macpherson Grant, Mr. J. E. Harting exhibited some curiously abnormal horns of the Roe Deer (the result of disease), which had been taken from an animal found dead near Forres, N.B. For the purpose of comparison he exhibited some normal heads of the Roe from other parts of Scotland and Germany, and made some remarks on the causes of variation in the size and form of the antlers to which Roe Deer were peculiarly liable.—A paper was then read by Mr. Spencer Moore on the true nature of *Callus*, and in continuation of former remarks on the same subject (Linn. Soc. Journ., Bot., vol. xxvii., Nos. 187–188). He showed that the outer sieve-plates of the fig are obliterated by a substance giving all the dye reactions of *Callus*, which does not peptonize and will not yield proteid reactions. Many of the inner sieve-plates he found to be stopped up with a proteid *Callus* resembling in every way the substance of *Ballia* stoppers, and the proteid *Callus* of the vegetable marrow. It appeared that true *Callus* would dissolve in a solution of gum-arabic, but whether by agency of a ferment or of an acid he had not yet determined.—A second paper by Mr. Spencer Moore dealt with the alleged existence of protein in the walls of vegetable cells, and the microscopical detection of glucosides therein.

PARIS.

Academy of Sciences, June 22.—M. Duchartre in the chair.—Method for the determination of the equatorial co-ordinates of the centres of the plates which are to form the photographic map of the heavens, by M. Lœwy.—On a generalization of equations relating to the theory of the functions of a complex variable, by M. Émile Picard.—On the determination of the mechanical equivalent of heat, by M. Marcel Deprez. At the meeting of June 8, M. Miculesco described an apparatus he had employed for determining the mechanical equivalent of heat. It is now remarked that the same method was employed by Hirn in the experiments made by him in 1860, and in latter years by M. d'Arsonval.—On the formation of the leaves of *Æsculus* and of *Pavia*, and on the order of appearance of their first vessels, by M. A. Trécul.—On the apparent and real glycolytic fermentation in the blood, and on a rapid and exact method of estimation of glycogen in the blood, by MM. R. Lépine and Barral.—On a telephone receiver of reduced weight and dimensions, by M. E. Mercadier.—Observations of the new asteroid discovered at Nice Observatory on June 11, by M. Charlois. Observations for position were made on June 11 and 12.—Observations of the same asteroid made at Algiers Observatory with the telescope of 0·5 metre aperture, by MM. Rambaud and Sy. Observations for position were made on June 12 and 13.—Extraordinary luminous phenomena observed on the sun, by M. E. L. Trouvelot.—On the determination of spiral surfaces according to their linear element, by M. L. Raffy.—On certain systems of spherical co-ordinates, and on the corresponding triple orthogonal systems, by M. A. Petot.—On the damping of Hertz vibrations, by M. V. Bjerknes.—Transmission of light across disturbed media, by M. A. Hurion.—On the electrolysis of barium chloride, pure or mixed with sodium chloride, by M. C. Limb. With moderate currents the author fails to obtain metallic barium; with the pure salt an infusible body of high resistance is deposited; with the mixed salts chlorine is disengaged at the anode, and, from the results of analyses given, it would appear that among the products of the electrolysis some subchloride must be formed.—The calculation of the temperature of ebullition of any liquid whatever, under all pressures, by M. G. Hinrichs.—Action of heat on solutions of chromium salts: green salts of chromium, by M. A. Recoura.—The constitution of the green chromium salts is elucidated by means of the results of experiments following thermochemical methods.—Researches on osmium, osmiamic acid, and osmiamates, by M. A. Joly. Taking the revised atomic weight of osmium, the analyses of Fritzsche and Struve, as well as those of the author, point to $KNOsO_3$, and not to $K_2N_2Os_2O_5$, as the formula denoting the composition of potassium osmiamate. Relations may be traced between osmiamic acid and the nitroso-compounds of ruthenium, $RuNOCl_3$ and $RuNO(OH)_3$. $O{=}OsNO{-}OH$ may be viewed as the first anhydride of the hypothetical $OsNO(OH)_3$.—On the alkaline zirconates, by M. L. Ouvrard.—On the bromo-iodides of silicium, by M. A. Besson.—On the cyanogen compounds of magnesium, by M. Raoul Varet.—On the action of nitric acid of different degrees of concentration upon iron at various temperatures, by MM. Henry Gautier and Georges Charpy. The writers conclude from their experimental results that "*iron is always attacked by nitric acid, whatever its concentration.*" The action may proceed in two ways—(1) rapid, and accompanied by the disengagement of gas; (2) slow, and without evolution of gas. The latter corresponds to what is known as the passive state of iron.—Action of sodium benzylate upon camphocarbonic ether, by M. J. Minguin.—Comparative influences of the sulphates of iron and calcium on the preservation of nitrogen in naked soils and on nitrification, by M. P. Pichard.—On the value of animal *débris* as nitrogenous dressing, by MM. A. Muntz and A. C. Girard.—On the development of blastodermic leaves in Crustaceæ Isopodæ (*Porcellio scaber*), by M. Louis Roule.—On the disengagement of oxygen by plants at low temperatures, by M. H. Jumelle. It appears that in plants capable of resisting excessive humidity or cold the decomposition of carbon dioxide may continue at very low temperatures, even when respiration has ceased. Conifers such as the juniper-tree, and a lichen (*Evernia prunastri*), in light can assimilate the carbon in the air in an atmosphere having a temperature as low as -30° or -40° C.—The parasitic fungi of Acridians, by MM. J. Kunckel d'Herculais and C. Langlois.—On the supposed post-Secondary granites of Ariège, by M. A. Lacroix.—On the age of a porphyritic granite from the Western Pyrenees, by M. Joseph Roussel.—Experimental researches on muscular exertions, by M. Charles Henry.—Diseases of the bones of chimpanzees, gorillas, and orang-outangs, by M. Etienne Rollet.

THE UNITED STATES ENTOMOLOGICAL COMMISSION.

Fifth Report of the United States Entomological Commission on Insects Injurious to Forest and Shade Trees. By Alpheus S. Packard, M.D., Ph.D.

VERY valuable Reports have been presented by the United States Entomological Commission from time to time. Among these may be mentioned that upon "The Rocky Mountain Locust," prepared by Prof. Riley in 1878, which is a most exhaustive record of the habits of this terrible pest, and of methods of prevention and remedies against its attacks. Later on, an equally valuable and instructive Report was submitted with regard to the cotton worm (*Aletia argillacea*), very destructive to the cotton plant, whose crop it has reduced in some seasons from 30 to 75 per cent. in the principal cotton-producing States. Both these elaborate works, as might be expected from their authors, Prof. Riley and Dr. Packard, who practically constituted this Entomological Commission, are full of interesting experiments, ingenious contrivances, and subtle devices, to circumvent the insect hordes advancing with the insistance of invading armies.

This Report upon "Insects Injurious to Forest and Shade Trees" is perhaps not so exciting or painfully interesting, as the harm caused to trees is not so directly felt as that occasioned to various food crops and other crops of the field by locusts and caterpillars innumerable, and the name of the insects described therein is legion, and their individual mischief is comparatively small.

As Dr. Packard says, "a volume could be written on the insects living on any single kind of tree, and hereafter it may be expected that the insect population of the oak, elm, poplar, pine, and other trees will be treated of monographically." Kaltenbach, in "Die Pflanzenfeinde, aus der Klasse der Insekten," gives accounts of 537 European species of insects injurious to the oak, 107 to the elm, and 396 to the willow. Perris, a French observer, has recorded no less than 100 species of insects found upon the maritime pine.

The attacks of insects upon forest trees and upon shade trees, or trees planted for shade and ornamentation in parks, streets, and other public places, are becoming far more numerous and serious, just as in the case of all cultivated crops under the sun. In the United States these attacks are creating intense interest, as the forests are of the highest commercial importance, and have been extensively decreased by clearing, by wanton and accidental fires, and other causes. This Report, then, is opportune, and must be of great service, as it demonstrates the sources of the injuries, and suggests means of preventing them or of diminishing them.

The French, German, Austrian, and Italian Departments of Agriculture are giving much attention to this subject, for it is found that the forest trees of these countries are becoming more liable to harm from insects. In Great Britain some kinds of trees, notably of the pine tribe, have suffered much damage from insects hitherto unknown, or, at least, not reckoned as injurious. There are, without doubt, many others unsuspected in British woods and forests, slowly but surely working great mischief.

Dr. Packard shows that trees are attacked in every part and in every conceivable manner by insects. Their roots, leaves, bark, fruit, and twigs are all more or less subject to their visitations. The most curious of those which affect the roots is the "seventeen year" Cicada, whose larvæ remain for over sixteen years attached to the rootlets of the oak, other forest trees, and fruit trees, as the pear and apple. According to Prof. Riley, these larvæ are found at a great depth, sometimes as much as 10 feet below the surface. The female, resembling a locust, deposits long slender eggs in an unbroken line upon the terminal twigs of oak and other trees in May and June. Sometimes the twigs are so "badly stung" by this oviposition that the trees are seriously injured. The length of wood perforated on each branch sometimes varies from one to two and a half feet, averaging probably eighteen inches, and appearing to be the work of one female. From the eggs the larvæ hatch out in six weeks and drop to the ground, in which they live, sucking the roots of the trees for nearly seventeen years, the pupa state lasting but a few days.

A formidable enemy of the "live-oak" (*Quercus virens*) is an enormous beetle, *Mallodon melanopus*, Linn., whose larva, three inches long and an inch in thickness, bores into the roots upon which it lives. As a result of the work of this insect in South Georgia and Florida, "vast tracts, which might otherwise have become forests, enriching the ground with annual deposits of leaves, are reduced to comparatively barren scrub, in which the scattered oak-bushes barely suffice to cover the surface of the sand." The eggs are laid by the beetle in the foot, or collar, of the tree, just below the surface of the ground. It is not known how long the larvæ live, but their life must extend over several years, "since the roots occupied by them grow to a large size, while they show an abnormal development, and become a tangle of vegetable knots. In fact, the entire root in its growth accommodates itself to the requirements of the borer within." The effect on the tree is to kill the original stem, which becomes replaced by a cluster of insignificant and straggling suckers, forming, perhaps, a clump of brushwood.

Among the tree-borers, other than beetles, the oak "carpenter worm," the caterpillar of *Prionoxystus robiniæ*, Peck, is the largest and most destructive. It is larger and far more abundant than the European caterpillar of *Cossus ligniperda*, or goat-moth, belonging to the same family of Cossidæ, but it sinks its tunnels deep in towards the heart of the tree, not confining its mischief to the limbs and large branches like the goat-moth caterpillar. Fitch says of this:—"Of all the wood-boring insects in our land, this is by far the most pernicious, wounding the trees most cruelly. The stateliest oaks in our forests are ruined, probably in every instance where one of these borers obtains a lodgment in their trunks." Another species of Cossus, known as *Cossus centerensis*, bores into poplars. Its appearance and habits also resemble those of the goat-moth, well known in this country.

There are numbers of boring beetles, of the families Buprestidæ, Cerambycidæ, and Scolytidæ, whose larvæ make burrows, passages, and galleries in trees, mainly just under the bark. Of these, the elm-tree borer, *Saperda tridentata*, is prominent, often killing elm-trees by wholesale, both in forests and in public parks. The larvæ bore in the inner bark, making irregular furrows and tunnels upon the surface of the wood, which "is, as it were, tattooed with sinuous grooves, and the tree completely girdled by them in some places." In the State of Illinois attention was attracted to the gradual decay and death of white elms (*Ulmus americanus*) in rows in some towns. The leaves fell off in the summer, and some of the branches died. Finally, the tree perished altogether. On peeling off the bark, half-grown larvæ of *Saperda tridentata* appeared in considerable numbers, and the manner in which the bark had been mined by the Saperdas gave sufficient evidence of the cause of the death of the tree. Prof. Forbes, State Entomologist of Illinois, says: "From the present appearance of the elms throughout the towns of Central Illinois, it seems extremely likely that this pest will totally exterminate this tree, unless it be promptly arrested by general action." It is recommended that all affected trees should be removed and destroyed in autumn and winter, before the beetles have a chance to emerge from the trunks. This beetle is not quite an inch long; its larva is rather more than an inch in length, having a large flat head.

Fir trees, especially the white pine (*Pinus strobus*), the yellow pine (*Pinus mitis*), and *Pinus rigida*, are much injured by the pine borer or "sawyer," *Monohammus confusor*. "I have seen," writes Dr. Packard, "hundreds, perhaps nearly a thousand, dead firs, whose trunks were riddled with the holes of these borers." Dr. Packard cites a correspondent of the *North-Western Lumberman* who reported that "extensive and valuable forests of yellow pine in the Southern States are destroyed by a worm commonly called here a 'sawyer,' or flat head." White pine trees are also much beset by the "wood engraver" bark beetle (*Xyleborus xylographus*, Fitch), so called because it makes beautifully regular and artistic furrows on the surface of the wood under the bark. It is the most common, and probably the most pernicious, of all the insects that infest the forests of white pine in New York State, and of yellow pine in the States south of New York.

A weevil, the white pine weevil (*Pissodes strobi*), frequently spoils the finest white pines in parts of America by placing numerous eggs in the bark of the topmost shoots of fir trees; the larvæ from these make mines in the wood and pith, causing the shoots to wither and die, thereby occasioning a fork, or crook, at this point. This is a very small insect, not three-quarters of an inch long, and the larvæ are not half an inch in length.

There is a mighty army of caterpillars of various moths described in this Report, which devour the foliage of trees of all kinds in American forests and gardens. Several species of Clisiocampa and Gasteropacha, of the Bombycidæ, assail oak, willows, ash, chestnut, apple, and pear trees. These are termed "tent" caterpillars, as they live in webs of a tent-like form, as the *Clisiocampa Neustria*, or lackey moth, in Europe. But the most voracious of caterpillars are the "fall web worms" of the moth *Hyphantria cunea*, Drury. For instance, in 1886, the city of Washington, as well as its vicinity, was entirely overrun by them. All vegetation, except that not agreeable to their tastes, suffered greatly. Fine rows of shade trees, which grace the streets and avenues, were leafless in midsummer, and covered with hairy worms. The pavements were strewn with moultings of the caterpillars and their webs, which were blown about unpleasantly by the wind.

Because they are hairy they have comparatively few enemies, among birds at all events. The "English sparrow," fast becoming as great a nuisance in the United States as the rabbit in Australasia, will not look at them, and has driven away by its pugnacity many birds that would eat them. Fortunately there are insect enemies which prey upon them, as the *Mantis carolina*, or "rear horse," an extraordinary insect of the same family as the "praying" mantis, and the "wheel bug" (*Prionidus cristatus*). Several parasitic insects also greatly check the spread of this moth. One fly, *Telenomus bifidus*, Riley, lays its egg within the tiny egg of the moth, in which all the transformations of the fly take place, and its food and lodging are found. In due time, having cleared out the egg, the fly emerges.

Mr. Bates, in his graphic account of tropical insects, has pictured many that are made to closely resemble their surroundings, for their preservation and other purposes. In his well-known paper on mimicry, he alludes to the insects known as Phasmidæ, or "spectre" insects, as especially typical of this adaptation to circumstances, preserved and augmented, as Darwin says, "through ordinary selection for the sake of protection." Mr. Wallace brings forward the Phasmidæ as striking instances of mimicry, remarking that "it is often the females alone that so strikingly resemble leaves, while the males show only a rude approximation."

Species of this family of Phasmidæ are mischievous to trees in America, principally the oak and the hickory. The chief of these is the *Diapheromera femorata*, Say., popularly called "walking-stick," "walking-leaves," "stick-bug," "spectre," "prairie alligator," "devil's horse." This insect, especially the female, is so like the twigs of trees in colour and appearance, that it is difficult to discover it. It has a habit, too, of stretching out the front legs and feelers, greatly enhancing this resemblance. While the vegetation is green the "walking-sticks" are green; when the foliage changes in the autumn they also change colour; and when the trees are bare of leaves they closely resemble the twigs on which they rest. The eggs are dropped upon the ground from whatever height the females may be, "and, during the latter part of autumn, where the insects are common, one hears a constant pattering, not unlike drops of rain, that results from the abundant dropping of these eggs, which in places lie so thick among and under the dead leaves that they may be scraped up in great quantities." Prof. Riley adds, with regard to these singular creatures and their wonderful resemblance to the oak vegetation upon which they occur, "one cannot help noticing still further resemblances. They are born with the bursting of the buds in the spring; they drop their eggs as the trees drop their seeds, and they commence to fall and perish with the leaves, the later ones persisting, like the last leaves, till the frost cuts them off."

There is not space enough to do more than allude to the sawflies, another class of insects fearfully injurious to trees of divers kinds. Many of these Hymenoptera, as in Great Britain and other European countries, mainly of the genus *Nematus*, clear off the leaves of forest and fruit trees. Others attack firs, notably some species of Lophyrus and Lyda, as the *Lophyrus abietis*, *Lophyrus pinetum*, and *Lophyrus pini-rigidæ*, and some of the Lyda. Cameron, in his monograph of the British phytophagous Hymenoptera, states that there are fifteen species of Lophyrus in North America, and that the species of Lyda are common there.

Lophyrus abietis and *Lophyrus abbotii* appear to do the same harm in America to firs as the *Lophyrus pini* in Scottish fir plantations, whose larvæ not only eat the leaves but the bark of the young shoots, frequently occasioning great losses.

An instructive account is given in this work of the effect of temperature upon insects. It is the fashion in Great Britain to say that insects are killed by hard frosts. But they are not killed in countries—as America, for example—whose winters are far more severe. Dr. Packard, quoting Judeich and Naitsche's "Lehrbuch der Mittel-Europäischen Forstinsektenkunde," observes that "the influence of even very great cold on the normal hybernating stages of our insects is not very great. In the summer of 1854 the 'nun' moth had very generally laid its eggs in Eastern Prussia uncovered on the bark, and these did not freeze in the hard winter of 1854–55. According to the observations of Regener, openly exposed caterpillars of the pine silk-worm endured 10° F. The pupa froze at 21° F., the moth at 19° F. According to Duclaux, the eggs of the silk-worm endure well, remaining two months in a temperature of 17° F. Great fluctuations of temperature during the winter produce an abnormal interruption of the winter's rest or hibernation, and thus cause the death of many insects." It will be noticed that in all these cases the insects were unprotected, whereas there is generally some kind of protection during the winter for insects in all stages, provided by their instinct.

Not the least useful part of the Report is that treating of remedies for insect attacks, and machines and engines for applying them. Arsenical poisons, known as Paris Green and London Purple, are strongly recommended for spraying or syringing trees infested with the larvæ of beetles and sawflies, or the caterpillars of moths. These have been recently introduced into England, being advocated by the Board of Agriculture, but have not been extensively adopted yet, owing to the natural prejudice against the use of poisons. In America they are employed most extensively and with the greatest benefit. By means of these the potato beetle (*Doryphora decemlineata*) was circumvented, and the cotton and boll worms checked, and the onslaughts of many other insects materially lessened. For Aphides, Scale insects, and other insects which suck the sap of leaves, "emulsions" or washes of soft soap, or "jelly soaps," made directly from fish oil and concentrated lye, or whale-oil soap, are prescribed. Also kerosine, naphtha, and petroleum, applied in a fine spray, or mixed with soap and soap jelly, forming "emulsions." These remedies act by contact, being applied principally to insects which do not eat the leaves, as well as by making the surroundings unpleasant and unbearable. Powdered substances, as pyrethrum, hellebore, and sulphur, are not much employed for forest work, but cases frequently arise warranting their use in a limited way. Hellebore, as gooseberry growers in Kent and Cambridgeshire well know, is of especial value against all sawfly larvæ. Sulphur is valuable against the red spider (*Tetranychus telarius*), and is used alone or in connection with emulsions of kerosene.

Numerous machines are in vogue for putting on washes and powders, from the small "knapsack" machine carried on the back, to huge tanks on wheels, fitted with powerful hand-pumps and long lengths of hose, through which liquids are forced to great heights; for very high trees, tall ladders are used, which are set near the trees, upon which men mount, and direct the hose into the topmost branches. For smaller trees and shrubs, a barrel fixed on wheels, having a good force-pump with hose, is adopted. Pumps are also fitted into tanks of all shapes and sizes, and moved from place to place by hand or horse-power. To distribute the liquids there are endless nozzles or jets contrived with much ingenuity to send forth fine mists, or sprays, or continuous volumes. It will suffice to say that the best of these is the cyclone, or Riley nozzle, which is just being introduced into Great Britain.

Foresters, and all concerned in the management of woods and forests, public parks, and gardens, would do well to consult this work for information as to the various insect enemies of trees, and the best means of dealing with them. It is quite impossible in a review to give anything more than a general idea of its scope and nature.

PHYSICAL RELIGION.

Physical Religion. The Gifford Lectures delivered before the University of Glasgow in 1890. By F. Max Müller. (London: Longmans, 1891.)

THE present volume, which embodies the author's second course of Gifford Lectures, with notes and appendices, is devoted to the consideration of "Physical Religion," that is the religion which finds its object the Infinite in or behind the phenomena of Nature. The author's previous writings have made it clear that for the simplest and most abundant manifestation of this form of religion we must go to the Veda, so his first task in the lectures before us is to tell once more the familiar story of the discovery, the character, and the age of the Veda. To this survey four lectures are devoted, and, in conclusion, the author—not without duly considering all that in recent years has been urged to the contrary—reaffirms his conviction that the hymns of the Rig Veda cannot have been collected later than 1000 B.C.

In the sixth lecture the author deals with the evolution of the idea of God. It is often supposed—even by philosophers of repute—to be a sufficient account of the earliest form of religion to say that men worshipped stones and other fetishes as their gods. But, as the professor well remarks—

> "Does it never strike these theorizers that the whole secret of the origin of religion lies in that predicate, *their gods?* Where did the human mind find that concept and that name? That is the problem which has to be solved; everything else is mere child's play."

And he exhibits the process by which Agni (the Vedic god of fire), from being originally nothing but "the mover," came to be called *deva;* and it is this word *deva* which when examined yields the clue to the development, and teaches us a lesson of the highest importance:—

> "Guided by language we can see as clearly as possible how, in the case of *deva*, the idea of God grew out of the idea of light, of active light, of an awakening, shining, illuminating, and warming light. We are apt to despise the decayed seed when the majestic oak stands before our eyes, and it may cause a certain dismay in the hearts of some philosophers that the voice of God should first have spoken to man from out the fire. Still, as there is no break between *deva*, bright, as applied to Agni, the fire, and many other powers of nature, and the *Deus optimus maximus* of the Romans—nay, as the God whom the Greeks ignorantly worshipped was the same God whom St. Paul declared unto them—we must learn the lesson, and a most valuable lesson it will turn out to be, that the idea of God is the result of an unbroken historical evolution, call it a development, an unveiling, or a purification, but not of a sudden revelation."

The two following lectures are devoted to the detailed following out of the biography of Agni, who appears in a variety of characters as the sun, the fire on the hearth, lightning, the messenger between gods and men, and priest. Finally, divested of his material character altogether, he is raised to a sublimer level as creator, ruler, and judge. The value of this inquiry, into the details of which we have no space to enter, lies in the fact that it involves the refutation of two objections which are frequently urged—with or without knowledge—against natural religion by the professors of so-called supernatural religion. The first is that natural religion, though it may lead men to a conception of "gods," is powerless to suggest to them the conception of God. This is directly contradicted by the history of Agni, whom we can watch, as it were, passing through many stages of growth until he becomes in the end "a supreme god, *the* Supreme God, till his very name is thrown away, or is recognized as but one out of many names by which ancient seers in their helpless language called that which is, the One and All." Driven from this position, however, the orthodox objector usually takes up another, and contends that the supreme God of natural religion lacks some if not all of the lofty attributes which he is enabled to know and to predicate of his own God by supernatural revelation. But Prof. Max Müller's answer to this objection is equally decided:—

> "Trusting to the fragments that have been preserved to us in the Veda, to the remains of the most childish as well as the most exalted thoughts, we may say that natural religion, or the natural faculties of man under the dominion of the natural impressions of the world around us, can lead, nay, has led man step by step to the highest conception of deity, a conception that can hardly be surpassed by any of those well-known definitions of deity which so-called supernatural religions have hitherto claimed as their exclusive property."

In the ninth lecture the Professor leaves for a while the field of his special studies to glance at the history of religious ideas among other peoples than the Âryas of the Veda. And it is noteworthy that he fully recognizes the possibility that Jehovah himself may originally have been a god of fire. But we must protest against the way in which he alludes to Abraham, the legendary founder of Hebrew monotheism, as if his historical character had never been questioned. It is, of course, perfectly open to any one to believe that Abraham was a real individual, who received a "revelation," whatever that word may be defined to mean (see p. 221); but at the same time, in a course of lectures addressed to an academic audience, it should surely have been mentioned that this is an hypothesis, which Renan, for instance, among Semitic scholars, does not even take the trouble to discuss.

In the lecture on the mythological development of Agni, we would call attention to the importance assigned to *riddles* as a cause of the growth and preservation of mythology. To take a simple example:—

> "After the Âryas in India had once arrived at the conception that fire was apt to consume the fire-sticks, or that Agni had eaten his father and mother, they seem to have amused themselves by asking such questions as, Who eats his own parents? The answers given would then enter upon many details, more or less far fetched, and the question would continue to be asked between young and old people."

And we think that this is a far more natural explanation of the origin and popularity of such stories than the hypothesis, which has no external evidence to support it, that the Âryas were simply ascribing to Agni the atrocities which they practised themselves.

Finally we come to the question, What can a study of natural religion teach us? "Why," answers Prof. Max Müller, "it teaches us that religion is natural, is real, is inevitable, is universal," and he proceeds to exhibit in detail one or two of the more important implications of this great lesson. With regard to miracles, for instance:—

> "Is it not clear that in the eyes of those who believe in the omnipresence of the Moral Governor of the world, miracles, in the ordinary sense of the word, have become impossible, and that to them either every event is miraculous or no event can claim that name. Before the great miracle of the manifestation of God in nature, all other miracles vanish. There is but one eternal miracle, the revelation of the Infinite in the finite."

The Professor then shows by a series of examples that the tendency to ascribe a miraculous birth to the founders of religions is natural and widespread, and asks by what right people claim a different character for the legends of the birth of Jesus than for the similar legends told of Buddha and Mohammed. The honesty and candour with which the question is stated are specially welcome at the present time, when it is becoming the fashion with ecclesiastical amateurs in Biblical criticism to blow hot and cold, as it were, with the same infallible mouth—that is, to reject the miracles of the Old Testament, but retain those of the New. For instance, in a recent manifesto, highly recommended as providing a temporary shelter for the destitution of the semi-reasonable, there is, on the one hand, some tall talk about the imaginative performances of "a dramatizing Jew" in the Old Testament, while, on the other hand, we are gravely informed that "the Church can insist upon the truth" of all that is recorded in the New Testament. That this cheap substitute for criticism will eventually be discredited, even in England, we have no doubt whatever. Meanwhile we cordially recommend the present volume not only for the interest of its subject-matter, but as an example of the masterly application of the only method which in these inquiries can lead to sure results.

THE KARWENDEL ALPS.

Das Karwendelgebirge. Von A. Rothpletz. Separat-Abdruck aus der *Zeitschrift des Deutschen und Oesterreichischen Alpenvereins.* With Map. (München, 1888.)

THE Karwendel Alps are a mountain mass lying to the north of the valley of the Inn, between Innsbruck and Jenbach, and bounded on the east by the Achensee, on the north and west by the upper valley of the Isar, and on the south roughly by a line drawn along the Hinterauthal (the highest part of the valley of that river) to Schwaz, in the Innthal. This region has been explored and mapped by Herr Rothpletz, with the assistance of other workers, and it is described as consisting of three roughly parallel ranges. Though their peaks do not attain to a very great elevation, the higher summits ranging from 6500 feet to rather over 8200 feet, their grand cliffs of cream-coloured limestone and their pine-clad slopes afford very beautiful scenery.

In this part of the Alps the mountain masses are wholly composed of sedimentary deposits which range from the Trias to the Neocomian. The oldest are the *Werfener Schichten*, a mass of sandy shales and sandstones, often containing numerous flakes of biotite, indicative, in all probability, of the denudation of the crystalline masses which form the floor of the Mesozoic rocks in the Alpine region. They correspond in age roughly with the upper part of the Bunter in Germany and England. Then comes the remainder of the Trias, including the Muschelkalk, followed by the representatives of the Rhætic, the Lias, and other Jurassic deposits, and a part of the Neocomian, a marine series from top to bottom. Neither the last nor the Jurassic system attains to a great thickness, but both the Rhætic and the Trias are represented by great masses of rock. In the one, the *Haupt-dolomit* occasionally attains to a thickness of 500 metres; in the other, one member, the *Myophorienschichten*, is said to be equally important. Careful descriptions of each subdivision, with lists of the more characteristic fossils, are given in the memoir. Neither Cretaceous nor Tertiary strata occur to bridge over the interval between the Neocomian and the superficial Glacial or post-Glacial deposits.

The physical history of these ranges is made the subject of an elaborate discussion. Herr Rothpletz is of opinion that, at some epoch after the Neocomian and before the commencement of the folding process by which the existing Alpine ranges were upraised, the region was affected by movements which produced a system of faults. In consequence of these, a zone of upheaval was bordered on either side by one of depression. These caused important modifications in the great east and west folds, to which the Eastern Alps are due; the rocks in the two troughs were crushed together; the upheaved tracts were upthrust. A folding plate represents an ideal section of the region after the "pre-Alpine" movements, side by side with one which shows its present state.

There can be no doubt that, in explaining the physical structure of the Alps, we have to take account of much more than the later Tertiary foldings to which the formation of the mountain-chain is due, such as the old irregularities of the pre-Mesozoic land-surface; and any important system of faults could not fail to produce very marked effects. Also, it seems indubitable that there were interruptions to the downward movement in parts of the Alpine area during the later Mesozoic and the earlier Tertiary times, which may, very probably, have caused faults such as are described by Herr Rothpletz. These, it may be noticed, appear to run obliquely to the general trend of the main folds.

Herr Rothpletz, in conclusion, expresses an opinion adverse to those geologists who consider that glaciers have played an important part in the erosion of valleys, and calls especial attention to the Soiernsee, a small lake lying in a fold of the *Plattenkalk*, which, in his opinion, indicates that "the movement of flexure acted in this case with greater rapidity than the erosive action of streams or glacier."

The geological map is on a scale of 1 : 50,000; the separate memoir, of octavo size, contains 76 pages, with 9 plates and 29 smaller illustrations. It also includes a full list of works bearing on the district. So far as we can judge, it is an elaborate and valuable contribution to the knowledge of a region but little known to English travellers, who, however, occasionally pass very near to it along the margin of the beautiful Achensee.

OUR BOOK SHELF.

Graphical Statics. Two Treatises on the Graphical Calculus and Reciprocal Figures in Graphical Statics. By Luigi Cremona. Translated by Thomas Hudson Beare, Professor of Engineering and Applied Mechanics, Heriot-Watt College, Edinburgh. (Oxford: Clarendon Press, 1890.)

TREATISES on this and allied subjects of the Graphical Calculus are not uncommon in our language; but, although nowadays indispensable for engineering purposes, the subject does not flourish in our theoretical courses of instruction.

The theorems of Graphics once stated—that is, drawn out carefully on the drawing-board—are obvious, or at least do not lend themselves to verbal written demonstration, so that for purposes of competitive examination, the controlling influence of modern education, the subject of Graphical Statics and Calculation is useless.

Geometrical drawing is not taught in our public schools and Universities; and the student in a technical college only requires the bare minimum of Graphics, sufficient to enable him to pass on to practical developments; so that we fear the elegant abstract theorems on the use of signs in Geometry, as applied to lines and areas, graphical multiplication, division, involution and evolution, solution of equations, centroids, rectification and graphical analysis generally, will receive but slight attention.

There is a note of defiance in the Author's Preface to the English edition of "Reciprocal Figures in Graphical Statics" (the second treatise): "At a time when it was the general opinion that problems in engineering could be solved by mathematical analysis only, Culmann's genius suddenly created Graphical Statics, and revealed how many applications graphical methods and the theories of modern (projective) geometry possessed," &c.

The preface to "Geometry of Position," by R. H. Graham, must be consulted for the counterblast in favour of Maxwell's claim to the honour of priority.

A. G. G.

The History of Commerce in Europe. By H. de B. Gibbins. With Maps. (London: Macmillan and Co., 1891.)

THE chief defect of this little book is that the author does not bring into sufficient prominence the geographical element in commercial history. What are the geographical conditions which have favoured the growth of particular industries in special localities? And in what ways have such conditions affected the interchange of commodities between one part of the world and another? Mr. Gibbins has not, of course, neglected these questions, but he scarcely seems to have realized that they are of vital importance for the scientific presentation of his subject. On the other hand, his appreciation of the action of historical causes in the development of commerce is excellent; and for a general view of commercial progress his manual will be of much service to students. After an introductory chapter he considers "ancient commerce," by which he means the commerce of the Phœnicians, the Carthaginians, and the Greek colonies. He then deals with the ancient Greek States and Rome as trading communities. Next comes "mediæval commerce," in connection with which he has much that is interesting to say about the Italian cities, the Hansa towns, mediæval trade routes and fairs, the manufacturing centres of Europe, and other topics. Under "modern commerce" he treats of the commercial empires in the East, the commercial empires in the West, English commerce from the sixteenth to the eighteenth century, European commerce in the seventeenth and eighteenth centuries, the industrial revolution in England and the Continental wars (1793), modern English commerce, and the development of commerce in France, Germany, Holland, Russia, and the other European States. The maps are very good, and add considerably to the value of the text. We may also note that the volume includes a useful series of questions on the various chapters, and two appendices, in one of which there is a list of British produce and manufactures in 1840 and 1889, while the other consists of a table showing the present colonial empires of European Powers.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Albert University.

THE remarks of Mr. Thiselton Dyer upon the draft charter of the "Albert University" have my fullest concurrence. I have never desired to see such a University as is sketched in that charter set up in London by the side of the existing University. The charter and the general scheme of its proposals never obtained the sanction of the professoriate of University College whilst I was a member of that body; and many of us were as active as circumstances allowed us to be, in opposing its federal principles and bureaucratic tendency. That University and King's Colleges should be united in some way to form a University is one proposition: that the University should take the particular form excogitated by Sir George Young is another. It is well that it should be generally known that the elaborate (and to my mind mischievous) constitution sketched in the draft charter of the Albert University is the product of the devotion and ingenuity of Sir George Young, an active member of the Council of University College.

I was not aware, when I wrote in NATURE some weeks ago on this subject, that the Lord President of the Privy Council had determined to set aside the recommendations of the late Royal Commission, and to hurry through a formal inquiry into the draft charter propounded by the Councils of University and King's Colleges.

So long as the matter was in the hands of the Commission, this charter, put forward by the Councils of the two Colleges, was merely one of many suggestions as to the proper form which a new or reconstituted University of London should take. It was notorious that the Councils' support of Sir George Young's scheme did not represent the attitude either of the Professors of the two Colleges or of those throughout the country who have special knowledge of Universities and of the best methods of academical organization.

The Royal Commission of 1888 was appointed to inquire "whether any and what kind of new University or powers is or are required for the advancement of higher education in London." The Commission took a large amount of evidence from interested parties—practically none from persons outside the London institutions concerned—and recommended that the University of London should be invited to meet the needs set forth in such documents as the draft charter of the Albert University, by some modifications of its constitution and procedure. In the event of a failure on the part of the University to do this, the Commissioners recommended *that the matter should be referred back to them.*

My support of the claim of University and King's Colleges to be incorporated as some kind of University has always depended on the assumption that no Commission or other serious authority could possibly accede blindly, and without full consultation of the best authorities in the land, to the scheme embodied in the Albert University draft charter. The Commissioners took, it seems to me, the only rational view of that charter—namely, that it might serve as a suggestion to the University in Burlington Gardens for a reform which would meet, at any rate, some of the objections raised to the existing constitution of the latter body.

Lord Cranbrook, however, seems anxious to hurry on the shelving if not the solution of the University of London question. Instead of referring the matter back to the Commissioners, he takes the matter out of their hands. The Commissioners have *never reported in answer to the question set before them.* No one knows whether they think any, and, if so, what kind of new University is required in London.

Having failed to settle the question for the time being by such a reform of the University in Burlington Gardens as Mr. Dyer advocates, the Commissioners ought—according to their own recommendation—to have been allowed to proceed further. "It is now ascertained," they would have said, "that the existing University of London will not reform itself in the way we have suggested: what sort of University shall we now recommend, if any?" They might have suggested the coercion of the Convocation of Burlington Gardens by an Act of Parliament; or they might have—after inquiring from authorities in Oxford, Cambridge, Dublin, Edinburgh, and wherever else some understanding of the nature and objects of Universities happens by chance to dwell—recommended the formation of a professorial University in London similar to those of Scotland and of Germany.

I confess that it has always been my hope, though not my expectation, that they would take the latter course. I am sure that if they had proceeded to take the evidence of experts in University matters, and had not attached undue importance to the proposals of competing corporations, they would have found the balance of unprejudiced opinion to be in favour of a "professorial" rather than a "federal" University. The difficulty they would have had to contend with would have been that some of their own body, and nearly every witness whom they lately examined, are very far from having a clear idea as to what are the possible forms of University organization, what the merits and the demerits respectively of the "federal" and the "professorial" scheme as now in practice in Europe. This is obvious enough from the printed "Minutes of Evidence taken before the Royal Commissioners appointed to &c.," which can be purchased of Messrs. Eyre and Spottiswoode for about half-a-crown.

But whatever else the late Royal Commission might have done, I cannot believe that they would have proposed to set up so extraordinary and useless a piece of complicated machinery as the Albert University (of the draft charter) by the side of Burlington Gardens. The draft charter, having failed to reform the existing University of London, ought, one would have thought, to have been torn up.

I quite agree with Mr. Dyer that it is little short of monstrous for the Government to set up in London *two* such organizations as Burlington Gardens and the federal Albert; there is the strongest reason for insisting that there shall be only one of them, whether Convocation likes it or not.

Meanwhile, we are no nearer than we were seven years ago to the formation in London of a Senatus Academicus which shall retain in the metropolis—in contact with its statesmen, lawyers, physicians, authors, and the intelligent men and women of wealth and leisure—the strongest and best of our scholars, historians, physicists, and biologists. Is it well that the President of the Royal Society of London should have to travel from Glasgow to the meetings of that body? that its senior Secretary should spend his life in Cambridge? and that there is absolutely no professorship in the metropolitan area which can, by virtue of its dignity or its pecuniary value, entice men from the seclusion of provincial Universities? The draft charter of the Albert University does not even attempt to supply such a want. It actually makes the London professor more a creature of competition and the servant of red-tape officialism than he is at this moment.

E. RAY LANKESTER.

Mr. THISELTON DYER has done good service in pointing out the nature of the proposed Albert University, which, unfortunately, seems not unlikely to be the result of the discussions that have been going on for the last six or eight years with respect to a "Teaching University for London." Should the charter petitioned for by the Councils of University and King's Colleges be granted, it will not constitute a teaching University in any real sense, but, as Mr. Thiselton Dyer says, an institution very similar to what the present University of London was as constituted by the original charter of 1837. There are, of course, differences of organization and machinery, such as the institution of Assemblies of Faculties and Boards of Studies (which the existing University might institute next week, if it saw fit), but there is little or nothing that can be looked upon as a difference of principle. The nearest approach to this are the provisions: (1) that the Colleges whose students are to be eligible as candidates for degrees shall have a certain amount of representation on the governing body of the University; (2) that the claim of additional Colleges to enter the University shall be decided by the governing body of the University, subject to appeal to the Queen in Council (instead of, as in the charter of 1837, being decided on directly by the Crown); (3) that "the University may appoint lecturers independently of a College or medical school to give instruction in any subject, whether it be or be not included in a Faculty."

With the exception of this last provision, slipped in at the end of Section V., "*University Degrees and Certificates*," as though modestly shunning the notice that a separate heading might call to it, there is no allusion from beginning to end of the draft charter to any teaching to be done by or through the University as such. If it comes into existence, it will be a mere examining University over again. Such a scheme can go no appreciable way towards remedying the existing defects of University organization in London. It is not easy to see what public advantages are likely to result from it. Seeing that it is put forward as representing the views of University College, London, it does not seem irrelevant to the present stage of the discussion to say that the scheme of the Albert University has never been submitted to a general meeting of the Governors of the College.

University College, London. G. CAREY FOSTER.

The Draper Catalogue.

ON p. 133 of the current volume of NATURE (June 11) Mr. Espin gives a comparison of the Draper Catalogue of Stellar Spectra with the catalogues of Vogel and Dunér. Vol. xxvi. of the *Harvard Annals*, of which the first part will be distributed in a few days, discusses at length the deviations from Vogel and also from the similar catalogue of Konkoly. A second examination was made on photographic plates having a long exposure of those stars which appeared discordant. Since spectra of the first type pass by insensible degrees into the second, and these in turn into the third, no two observers would agree on the exact points of distinction. Moreover, different characteristics would distinguish the photographic and visual portions of the spectra (*H. C. Annals*, xxvi. pp. 177, 189). Some discrepancies, as in the case of the three fourth-type stars which are erroneously entered in the Draper Catalogue, are due to errors of identification (xxvi. p. 192). The photographic spectra of faint third-type stars are always indistinguishable from those of the second type (xxvi. p. 178). See also remarks following Table II. of vol. xxvii. The bright lines cited by Mr. Espin are probably portions of the spectra contained between dark bands or lines (xxvii. p. 3). Spectra are difficult to classify when measured as faint as 6·5; not when the final magnitude is brighter than 6·5, as might be inferred from Mr. Espin's reference (xxvii., preface).

EDWARD C. PICKERING.

Cambridge, U.S., June 22.

The Cuckoo.

I DO not know if the hibernating of swallows and other summer visitors is still a debated question or not, but the following account of a cuckoo may be of interest to some of your readers.

In the month of August a young cuckoo was taken from its nest and kept in the house, where it lived and throve—until one day in November, when it escaped and could not be found. But in the following March, during the usual spring cleaning, this very bird was discovered on a shelf in the back kitchen, hidden away behind some old pots and pans, still alive, and asleep, with all its feathers off, and clothed only in down, the feathers lying in a heap round the body. The rude awakening which the cuckoo received was fatal to its existence, for it survived only for a few hours.

E. W. P.

Colour-Associations with Numerals, &c.

THE following record of experiments extending over a period of nearly ten years, under exceptionally good conditions, appears to me to be worthy of attention. A preliminary note on the subject was printed in *Science*, vol. vi. No. 137, 1885, p. 242, part of which is reproduced below.

In 1880, while I was in Washington, I read Mr. F. Galton's note on "Visualized Numerals," in NATURE, vol. xxi. p. 252.

After I came to Wisconsin—probably late in 1881, or early in 1882—I mentioned my own entire inability to visualize numerals or anything else of the kind to a member of the University faculty, Prof. Owen. I was interested to learn that, when a boy, he had always conceived the vowel sounds as having colour, and that he still retained some traces of this early habit.

I spoke of this subject in my house shortly after; and my daughter Mildred, then about seven years old, said she also had colours for the days of the week, as follows: Monday, *blue;* Tuesday, *pink;* Wednesday, *brown* or *grey;* Thursday, *brown* or *grey;* Friday, *white;* Saturday, *pure white;* Sunday, *black.* It was said laughingly, and at the time it passed to my mind as a joke—that she wished in sport to assume the idiosyncrasies of elder persons. A few days after, I questioned her on these colours, and she gave the same replies. It was again spoken of as a kind of a joke and a question of memory, but I wrote the colours down in my memorandum-book for 1882. A year later I produced this, and again questioned her—this time seriously—and found her answers the same as at first. Again, on August 5, 1885, her replies were the same. The tenacity of a child's memory is very remarkable; but I was convinced this was not a case of memory and imagination, but a true phenomenon of the kind referred to. I therefore went farther, and asked her if there were any other phenomena of the same sort (she was now ten and a half years old). I found that each of the letters of the alphabet had a colour to her, as follows:—

A, *white;* B, *blue;* C, *yellow, cream colour;* D, *dark blue;* E, *red;* F, *black;* G, *green;* H, *white;* I, *black;* J, *grey, brown;* K, *grey;* L, *dark blue;* M, N, *brown,* not much colour; O, *yellow;* P, *green;* Q (?); R, *brown;* S, *yellow;* T, *green;* U, *yellow;* V, *white;* W, *brown;* X, Y, not much colour; Z, *greenish.*

The prevalence of yellow and green, and the scarcity of reds and pinks, are noteworthy. I found that she knew these colours instantly, and when I asked for them in any order. What is more remarkable, she could instantly name the brown letters in a group, the black ones, &c. Apparently she did not require to pass the alphabet in review to decide this. The numbers also had colours to her, as follows:—

1, *black;* 2, *cream colour;* 3, *light blue;* 4, *brown;* 5, *white;* 6, *crimson, pink;* 7, *greenish;* 8, *white;* 9, *greenish* (?); 10, *brown;* 11, *black;* 12, *cream colour;* 13, *blue;* 14, *brown;* 15, *white;* that is, 11 had the same colour as 1, 12 as 2, 13 as 3, &c.

These colours were also named instantly, and in any order, and in groups.

Case of Miss Mildred Holden.

[1] If anything.

Note.—The column for June 1891 was sent to me in a letter, as written in the table, except that *Wednesday* and *Thursday* are described as "brownish-grey, with little dots," and *Friday* as "white, with dots." The letter says:—"Is this right? I write this out without giving much thought to it—writing as fast as I can write. I am not quite definite in my mind as to the colours of 9, 10, G, T, K, O, Q, S, V; but the others have never changed. The days of the week I *never* think of without thinking of their corresponding colours. They have always remained the same. I don't quite remember if I have ever told you about the dots before, but they have always been there, and are like minute pencil marks showing through the colour. *Tuesday* is slightly dotted."

The table gives the results of the earlier experiments together with others which have been subsequently obtained. The later experiments have been made under circumstances which are peculiarly favourable—usually by correspondence during my daughter's absence at school.

The table undoubtedly represents vivid and permanent associations of colour with numerals, letters, &c. If we collect the various signs which correspond to a given colour, it appears, on the whole and in a general way, that the colour is associated with the *sound* rather than with the *form* of a letter. For example, G, P, T, Z are *green;* A, H, eight, are *white;* V, Friday, five, are *white;* C, S, Saturday, are yellow, &c. There are numerous exceptions to this, however, and it is by no means proved that there is a real law here. I simply make the suggestion on account of its bearing on the question whether or no we can think without words. It is clear that many experiments, such as are exhibited in the table, must be made before the time will arrive for definite conclusions to be drawn. Perhaps this brief note may induce others to print the results of similar investigations.

EDWARD S. HOLDEN.

Mount Hamilton, June.

Erratic Barometric Depression of May 23-29, and Hailstorm of May 24.

In connection with the very interesting letter of the Rev. Clement Ley (on p. 150), descriptive of the barometric depression which passed over these isles towards the end of last month, the following extract from a letter of mine published in the local press, with a view of obtaining further information, but without success, may be of interest. At the time when the centre of the depression lay over the mouth of the Thames, as mentioned by Mr. Ley, this neighbourhood was being visited by a thunderstorm of great severity and lengthy duration, and at 6 p.m. the rain gave place to hail, and "In the short space of twenty minutes the ground and roofs of houses were covered with a compact layer of frozen rain-drops, which at the end of half an hour (6.30 p.m.), when the storm had abated and given place again to rain, I found to have an average depth of 0·75 inch, though the stones were then reduced to about half their original size. . . . But few of the hailstones, which were nearly all ovarious in form, were smaller than 0·375 by 0·250 inch, and three which I picked up at random at 6.10 p.m. when the storm was at its height, measured respectively 0·065 by 0·051 inch, 0·437 by 0·562 inch, and a spherical one had a diameter of 0·5 inch." Such large hailstones are, I believe, rarely met with in storms near London. This one seems to have been confined to a comparatively small area, the hail falling in its greatest severity at Leyton, and not extending much beyond Walthamstow, Stratford, West Ham, and here. B. J. Hopkins.

Forest Gate, E., June 22.

"An Alphabet of Motions."

I have lately found the following extract in Arthur Young's "Travels in France, in 1787," which I fancy is not generally known. It occurs in Betham Edwards's late edition (Bell and Sons), at p. 96.

"In the evening to Mons. Lomond. . . In electricity he has made a remarkable discovery. You write two or three words on a paper; he takes it with him into a room and turns a machine inclosed in a cylindrical case, at the top of which is an electrometer, a small fine pith ball; a wire connects with a similar cylinder and electrometer in a distant apartment; and his wife, by remarking the corresponding motions of the ball, writes down the words they indicate, from which it appears he has formed an alphabet of motions. As the length of the wire makes no difference in the effect, a correspondence might be carried on at any distance."

On a Cycle in Weather Changes.

It is known that Prof. Brueckner, of Berne, in a work on "Klimaschwankungen," published a short time ago, offers a large amount of evidence for the view that our globe is subject to a weather-cycle of about 35 years, a series of cold and wet years, or warm and dry ones, recurring at about that interval. Has it been noticed in this connection that Bacon, in one of his essays (No. lviii. "Of Vicissitude of Things"), makes reference to such a cycle? The passage is as follows:—"There is a toy which I have heard, and I would not have it given over, but waited upon a little. They say it is observed in the Low Countries (I know not in what part) that every five-and-thirty years the same kind and suit of weathers comes again; as great frosts, great wet, great droughts, warm winters, summers with little heat, and the like, and they call it the *prime*. It is a thing I do the rather mention, because, computing backwards, I have found the same concurrence." A. B. M.

THE FORECAST OF THE INDIAN MONSOON RAINS.

AFTER an interval of twelve more or less prosperous years, following on the memorable Madras famine of 1876–77, and the drought and fearful mortality of North-Western India in 1877–78, India seems once more to have entered on one of those prolonged series of adverse seasons which put a severe strain on the protective powers of its Government, and, despite all human precaution, bring suffering, disease, and premature death to thousands of its industrious peasants, and to even larger numbers of the impoverished outcasts who form the lowest fringe of its teeming population, fighting the precarious battle of their life at all times on the verge of destitution. The drought in Ganjam in the autumn of 1889 has been followed by the failure of the late autumnal rains over the central districts of the Carnatic towards the close of last year, and the too familiar machinery of relief works for the able-bodied, and doles of food to the helpless indigent, has been in active operation for several months past in the districts around Madras. Another monsoon, another season of those periodical rains on which depends the fate of millions, is now due and overdue, and there comes from India an ominous note of warning that there is reason to fear that more than one great province of the empire, or certain portions of them, may again this year lie parched and barren, their young crops withering and shrivelled under the dry west wind, while, month after month, men scan with ever-growing anxiety the pale dust-obscured sky and scattered ball-shaped clouds that never mass themselves to rain-clouds, but mock their hopes with the promise of showers that never fall to moisten the sun-baked soil.

And this warning, alas! is no mere guesswork of credulous and speculative minds, such as in these latitudes certain of our would-be weather prophets love to put forth at hazard, to furnish the topic of a day's gossip to the million, or haply to win for themselves a summer day's reputation with the uninstructed, in the event of a successful issue. Certainty, indeed, there is not and cannot be till science shall have extended its domain far beyond its present limits; but, in India, the stately march of the seasons is but little obstructed by the vicissitudes of fugitive cyclones and anticyclones, that originate we know not how, and disappear by some concurrence of causes equally beyond our ken. In the tropics, and in the realm of the monsoons, all weather phenomena are more massive and slower in progress, and each great change of seasons is heralded by signs which, if we can as yet but vaguely interpret them, are at least recognizable as such, and, with a certain allowance for possible error, must be accepted as timely monitors of what is likely to follow. These it is that, whether rightly or wrongly deciphered, furnish the basis for the present warning. To those who, like the present writer, have followed for many months past, not without anxious interest, the telegraphic and other reports periodically transmitted from India, it comes as no surprise, but as a confirmation of misgivings long entertained though only now backed by the warranty of full official evidence. The events of the next three months may yet belie the present indications, and that they may do so is still our fervent hope; but it would be folly to ignore them, and to shut our eyes to the probabilities that they seem to portend.

For the last eight years it has been one of the duties of the Indian Meteorological Department, some time early in June, to prepare, for the information of Government and the public, a forecast of the probable character of the summer monsoon, based on the reports of the snowfall on the Himalaya and the western mountains, and on the indications afforded by the weather of the previous winter and spring. The possibility of framing such a forecast was in a measure foreseen by the Famine Commissioners appointed by the Home Government after the disastrous famines of 1876 and 1877, of which Commission General R. Strachey, the true founder of the Meteorological Department of India, was the scientific member; and it is in no small degree due to the weighty advocacy of this Commission that the Department owes its present extension and importance. Mr. Eliot's forecast for the coming season is now before us. It sets forth at length the general and special grounds on which he bases his conclusions; and these, though duly guarded by the reminder of their essentially empirical character, and of the unavoidable imperfection of our information regarding certain important data, are expressed in terms that leave unhappily no doubt of the adverse character of the outlook.

Attention was first directed to the apparent connection of the Himalayan snowfall with the prevalence of dry land winds in India, in the year 1877, and about the same time the late Prof. S. A. Hill and Mr. Douglas Archibald showed that, as a general rule, an unusual cold weather rainfall in Northern India was followed by a deficient rainfall in the ensuing summer monsoon. In a paper published in the Proceedings of the Royal Society in 1884, these two classes of facts were shown to be merely different phases of the same phenomenon, and a summary was given of all the evidence on the subject that had been accumulated up to that date. Since then, there has been but one year of heavy Himalayan snowfall, viz. 1885, and in that year the rains were greatly delayed on the Bombay coast, and were very deficient in North-Western India in June, July, and September, commencing late, and terminating early. During the past winter and spring the snowfall on the North-Western Himalaya and the mountains of Afghanistan and Baluchistan has been excessive—indeed, as Mr. Eliot states, unprecedented during the last twenty-five years—and from the reports received from the civil officers and observatories in the mountain districts, he estimates that an average fall of 40 feet, if not considerably more, must have fallen over all the higher ranges, from Murree eastward to Garhwal, if not to Central Nepal. That it was the same on the less accessible range of the Hindu Kush we have reason to believe from the casual reports that were received during the last winter, and we know that in Southern Europe and even in Northern Africa, snow fell down to the sea-level, and was such as has hardly been experienced certainly during the greater part of the present century. The phenomenon has therefore been one of widespread incidence, and indicates some remarkable and rare condition of those higher strata of the atmosphere which, we have now reason to believe, are the seat of the more important changes that regulate the vicissitudes of the weather of the globe.

Concurrently with this exceptional extension of the snowfall to low latitudes of the temperate zone, the Indian registers afford evidence of certain abnormal features, which are such as have been noticed on former occasions of unusual snowfall on the North-West Himalaya, and the bearing of which on the weakness of the summer monsoon is more clearly traceable. In fact, they tend to link the two phenomena together, whether we regard them as the common effects of some more remote agency, or as displaying the different steps of a physical sequence of cause and effect. The most important of these are: the unusual rainfall over the whole of Northern India in the past winter and spring, amounting to from two to three times the average in the Punjab, where it was heaviest; a prevailing low temperature in Northern and especially North-Western India, together with a corresponding excess of temperature in Assam, Burma, and Southern India; and finally, a persistent excess of atmospheric pressure in the former region and a deficiency in the latter. These anomalous features have characterized more or less all the months of the present year, especially March and May. As estimated by European standards, the anomalies of this last element may indeed appear small. For instance, the mean excess at Peshawar in May was 0·052 inch, at Mooltan 0·041, and at Quetta 0·049 inch, while the deficiency at Calicut was 0·040 inch, and at Sibsagar 0·031 inch. Taken together, they constitute an anomalous gradient from north-west to south and east of something under a tenth of a barometric inch in distances of 1300 and 1500 miles. But in India such differences are relatively large, and, as former experience has abundantly shown, very significant. As temporary phenomena they might indeed be of little importance; but, lasting as they have done through nearly half a year, they point to an anomalous state of the atmosphere which is evidently persistent, and is distinctly adverse to the northern incursion of the summer monsoon. Taking the general mean of all parts of the empire, the atmospheric pressure has been above the average in every month of the present year. With respect to the winds, Mr. Eliot remarks:—"South-easterly winds have been unusually prevalent in Bengal and Behar during the months of April and May, and north-westerly and northerly winds on the west coast of India as far south as Cochin. The unusual prevalence of north-westerly winds on the Bombay coast in the month of May was one of the features of the weather in 1876, 1883, and 1885, in which years the monsoon was greatly retarded on that coast."

Finally, after reviewing the chief characteristics of other years in which the Himalayan snowfall has been heavier than usual, Mr. Eliot draws the following conclusions with respect to the probable character of the monsoon rains of the present year in the different provinces of India:—

"(1) Snowfall conditions on the Western Himalayas, &c., and the pressure conditions in India are very unfavourable to the establishment of a strong and early monsoon on the Bombay coast. It is very probable that it will not be established in full strength on the Bombay coast before the third or fourth week in June, and it is probable that it will be below its average strength, and may be withdrawn from Upper India earlier than usual in September.

"(2) The snowfall conditions in the Eastern Himalayas, and the pressure conditions in North-Eastern India and Burma, are favourable to the advance of a moderately strong or strong monsoon in the Bay of Bengal earlier than usual, and to its establishment in Burma and Bengal before or about its normal period," and Burma, Bengal, and Assam are expected to receive an average or more than an average rainfall; Behar and the eastern districts of the North-West Provinces about the usual amount. In Southern India it is thought probable that the rains may be retarded, but that Malabar and Southern India generally are likely to receive favourable rain during the monsoon.

On the other hand, it is pointed out that "conditions are very unfavourable for Rajputana, and also to some extent in Guzerat, the southern districts of the Punjab, and the western districts of the North-West Provinces. It is probable the rainfall will be more or less deficient over the whole of that area, and possible that the deficiency may be large and serious." In Northern Bombay and Berar it is thought that "the rainfall is more likely to be slightly deficient than up to its normal amount," and that in the Central Provinces it will be "fairly normal."
